## Introduction

Metapopulations exist along a continuum, with dynamics driven by the balance of extinction and colonization of local patches at one extreme and the balance of immigration at the other. In this paper, we focus on the balance of extinction and colonization, which is often referred to as the balance of dispersal. We will show that the balance of dispersal is a key factor in determining the persistence of a metapopulation.

tion and emmigration at constantly-occupied local patches at the other (Kritzer and Sale, 2006). Terrestrial metapopulations often show extinction-colonization dynamics (e.g. Hanski, 1998), while marine metapopulations tend to exhibit immigration-  
emmigration dynamics where local extinction of patches is uncommon (Kritzer and Sale, 2006). For these metapopulations, dynamics and persistence depend on connectivity among patches and the demographic rates at each patch (e.g. Hastings and Botsford, 2006a; Hanski, 1998). Assessing levels of connectivity and demographic parameters has been particularly challenging for marine species, where much of the mortality and movement happens at larval and juvenile stages when individuals are hard to track and have the potential to travel long distances with ocean currents (e.g. Kritzer and Sale, 2006; Cowen and Sponaugle, 2009; Roughgarden et al., 1988).

A need to understand metapopulations for conservation and management, such as siting marine protected areas (e.g. Botsford et al., 2001; White et al., 2010), however, has led to a large body of theory describing how marine metapopulations might persist.

For any population to persist, individuals must on average replace themselves during their lifetime. Assessing replacement must take into account the demographic processes across the whole life cycle, including how likely individuals are to survive to the next age or stage, their expected fecundity at each stage, and the survival of any offspring produced to recruitment. In a spatially-structured population, as many marine populations are, in addition to assessing whether the reproductive output and survival of a population is sufficient, we must also consider how the offspring are distributed across space.

27 Considering both the demographic processes within patches and the connectivity  
among them, a metapopulation can persist in two ways: 1) at least one patch can  
achieve replacement in isolation, or 2) patches receive enough recruitment to achieve  
30 replacement through multi-generational loops of connectivity with other patches in  
the metapopulation (Hastings and Botsford, 2006a; Burgess et al., 2014). In the first  
case (termed self-persistence), enough of the reproductive output produced at one  
33 patch is retained at the patch for it to persist. In the second (network persistence),  
closed loops of connectivity among at least some of the patches - where individuals  
from one patch settle at another and eventually send offspring back to the first in a  
36 future generation - provide the patch with enough recruitment to persist within the  
network. Though it has been challenging to estimate the parameters necessary to  
understand how actual metapopulations persist, a large work of theory developed in  
39 part to guide marine protected area design helps predict when each type of persistence  
is likely to occur (i.e., large patches relative to the mean dispersal distance are likely  
to be self-persistent, Botsford et al., 2001).

42 New ways of identifying individuals and determining their origins, such as otolith  
and shell microchemistry and genetic parentage analysis (e.g. Wang, 2004, 2014) are  
making it increasingly possible to estimate both the demographic (e.g. Carson et al.,  
45 2011; Hameed et al., 2016) and the dispersal (e.g. Almany et al., 2017; D'Aloia et al.,  
2013) parameters necessary to assess persistence in real metapopulations. We might  
expect that populations on isolated islands are the most likely to be self-persistent,  
48 as they lack nearby populations with which to exchange larvae and would go locally  
extinct if they did not achieve replacement. At isolated Kimbe Island in Papua New

Guinea, Salles et al. (2015) find that the population of orange clownfish (*Amphiprion percula*) can likely persist without outside immigration. In contrast, populations of bicolor damselfish (*Stegastes partitus*) at a set of reef patches across four isolated islands in the Bahamas do not appear able to persist without outside input (Johnson et al., 2018). For populations that exist in patches along a continuous linear coastline, rather than on separate islands, however, the scale of metapopulation persistence is still an open question.

The number of studies estimating demographic rates and connectivity in marine metapopulations is growing (e.g. Carson et al., 2011; Salles et al., 2015; Johnson et al., 2018; Garavelli et al., 2018), but most use data from one or a few years. Longer data sets enable better estimates of long-term average rates, rather than assuming the demographic and dispersal rates from a particular year or two are representative. Long data set are also useful for explicitly considering uncertainty, both to assess how well we understand persistence for a population and to assess which parameters contribute most to our uncertainty. Finally, sampling over many years provides abundance trends to compare with persistence metrics.

Here, we further our understanding of metapopulation dynamics in a network of patches along a coastline through a study of yellowtail clownfish (*Amphiprion clarkii*) in the Philippines. We assess persistence for all patches of habitat within a 30 km stretch of coastline, exceeding estimates of the dispersal spread for this species (Pinsky et al., 2010), suggesting the network is likely to operate as a contained metapopulation. With seven years of annual sampling data, we are able to estimate persistence metrics and replacement over the longer term and investigate abundance

through time to compare with the replacement-based persistence metrics. We use our long-term data set from habitat patches on a continuous section of coastline to  
75 understand persistence within a local network.

## Methods

### Persistence theory and metrics

78 For a population to persist, individuals must be able to replace themselves on average at low abundance (e.g. Hastings and Botsford, 2006a; Botsford et al., 2009). In non-spatially structured populations, we use criteria such as the average number  
81 of recruiting offspring each individual produces during its life (called  $R_0$  when the population is age-structured and density-independent) or the growth rate of the population (such as the dominant eigenvalue  $\lambda$  of an age-structured Leslie matrix) (Caswell, 2001; Burgess et al., 2014). For spatially-structured populations, we must  
84 also consider the spatial spread of offspring, often represented through a dispersal kernel or connectivity matrix (e.g. Cowen, 2006; Buston et al., 2011; Hogan et al.,  
87 2011; DAloia et al., 2015)).

We consider four primary metrics to assess whether and how the population is persistent: 1) lifetime recruit production (LRP), to assess whether the population  
90 has enough surviving offspring to achieve replacement, 2) self-persistence (SP), to assess whether any individual patch can persist in isolation without input from other patches, 3) network persistence (NP), to assess whether the metapopulation is per-  
93 sistent as a connected unit, and 4) local replacement (LR), as second assessment of

whether individuals replace themselves with recruits retained within population. We  
explain each metric below in detail. To represent the uncertainty in our estimates, we  
96 calculate each metric 1000 times, pulling each input parameter from a distribution  
or range. In our results, we show our best estimate of each persistence metric along  
with the range of uncertainty values.

### 99 **Lifetime recruit production**

We find the estimated number of recruits an individual recruit will produce (lifetime  
recruit production: LRP) by multiplying the total number of eggs a recruit-sized  
102 individual will produce in its lifetime (lifetime egg production: LEP) by the fraction  
of those eggs that will survive to become recruits (egg-recruit survival:  $S_e$ ) (Fig. 2):

$$LRP = LEP * S_e. \quad (1)$$

If  $LRP \geq 1$ , the population has the potential for replacement; individuals produce  
105 enough surviving offspring, before considering dispersal. If  $LRP < 1$ , the individuals  
are not replacing themselves and the population cannot persist without input from  
outside patches and is a sink habitat within a larger metapopulation (Pulliam, 1988).  
108 We use all recruits produced by adults in our population to estimate  $LRP$ , regardless  
of where they settle.

## Self-persistence

- <sup>111</sup> A patch is able to persist in isolation (self-persistent) if individuals produce enough offspring that survive to recruitment (LRP) and settle in the natal patch ( $i$ , with probability of dispersal  $p_{i,i}$ ) to replace themselves:

$$SP_i = \text{LRP}_i \times p_{i,i}. \quad (2)$$

- <sup>114</sup> A patch  $i$  is self-persistent if  $SP_i \geq 1$ . If at least one patch is self-persistent, the metapopulation as a whole is persistent as well (Hastings and Botsford, 2006a; Burgess et al., 2014). Our equation for SP is a modification of that used in Burgess et al. (2014), which uses LEP to represent offspring produced and uses local retention (the number of surviving recruits that disperse back to the natal patch divided by the number of eggs produced by the natal patch) to capture egg-recruit survival and dispersal combined:  $\text{LEP} \times \text{local retention} \geq 1$ . We modify this to include egg-recruit survival in the offspring term instead, using LRP in place of LEP.
- <sup>117</sup>
- <sup>120</sup>

## Network persistence

- <sup>123</sup> Network persistence explicitly considers dispersal of individuals among sites, a critical part of the larval life stage, in addition to the reproduction and survival at each site. We represent dispersal with a dispersal kernel, which relates the likelihood of an individual dispersing to the distance traveled. We find the probabilities of a
- <sup>126</sup>

recruit dispersing between each set of sites ( $p_{i,j}$ ) by integrating the dispersal kernel over the distances between sites. We then create a realized connectivity matrix  $C$  by multiplying the dispersal probabilities by the expected number of recruits an individual produces:  $C_{i,j} = \text{LRP} \times p_{i,j}$  (Burgess et al., 2014, though we include egg-recruit survival in LRP, rather than in  $p_{i,j}$  as they do). The diagonal entries of  $C$ , where the origin and destination are the same site, are the values of self-persistence for each individual site.

Network persistence evaluates the largest real eigenvalue of the realized connectivity matrix  $\lambda_C$ , which must be greater than 1 for the network to persist without outside input:  $\text{NP} = \lambda_C \geq 1$  (e.g. Hastings and Botsford, 2006a; White et al., 2010; Burgess et al., 2014).

### **138 Local replacement**

Like network persistence, local replacement (LR) assesses whether the population is locally self-sustaining. Rather than considering dispersal explicitly as network persistence does, local replacement modifies LRP to estimate the average number of recruits produced per individual that return to settle within our sites. We estimate LR by multiplying LEP by the proportion of eggs produced that survive and return to recruit at our sites ( $R_e$ ), a modification of egg-recruit survival that implicitly includes dispersal. If  $LR \geq 1$ , individuals produce enough locally-retained offspring to replace themselves and the population can persist in isolation.

$$\text{LR} = \text{LEP} \times R_e. \quad (3)$$

<sup>147</sup> **Study system**

We focus on a tropical metapopulation of yellowtail clownfish (*Ampiprion clarkii*, Fig. 3c) on the west coast of Leyte island facing the Camotes Sea in the Philippines (Fig. 150 3a). Like many clownfish species, yellowtail clownfish have a mutualistic relationship with anemones that house small colonies of fish (Buston, 2003b; Fautin et al., 1992). Yellowtail clownfish are protandrous hermaphrodites and maintain a size-structured 153 hierarchy; within an anemone, the largest fish is the breeding female, the next largest is the breeding male, and any smaller fish are non-breeding juveniles. The fish move up in rank to become breeders only after the larger fish have died. In the 156 tropical patch reef habitat of the Philippines, yellowtail clownfish primarily spawn from November to May, laying clutches of benthic eggs that the parents protect and tend (Ochi, 1989; Holtswarth et al., 2017). Larvae hatch after about six days and 159 spend 7-10 days in the water column before returning to reef habitat to settle in an anemone (Fautin et al., 1992).

Clownfish are particularly well-suited to metapopulation studies due to their limited movement as adults and clearly patchy habitat. Once fish have settled, they tend 162 to stay within close proximity of their anemones, which are found on reef patches. This makes fish easier to relocate for mark-recapture studies and simplifies the 165 exchange between patches to only dispersal during the larval phase. Patches, whether considered to be the reef patch or the anemone territory of the fish, are clearly discrete and easily delineated (Fig. 3a, b), which makes determining the spatial structure of 168 the metapopulation clear. Additionally, clear patches make it easier to assess how

much of the site has been surveyed. These simplifying characteristics in habitat and fish behavior make clownfish and other similarly territorial reef fish useful model  
171 systems for studies of metapopulation dynamics and persistence (e.g. Buston and DAloia, 2013; Salles et al., 2015; Johnson et al., 2018). Our focal species of yellowtail  
172 clownfish tends to behave more like larger reef fishes, with wider-ranging territories  
and stronger swimming abilities (Hattori and Yanagisawa, 1991; Ochi, 1989), than  
174 the smaller clownfish *A. percula* commonly used in previous metapopulation studies  
(e.g. Buston et al., 2011; Salles et al., 2015). As we show later, survival in yellow-  
177 tail clownfish is also lower than *A. percula* and more similar to other damselfishes.

MAKE SURE THIS SENTENCE IS TRUE!

### Field data collection

180 We focus on a set of seventeen patch reef sites spanning 30 km along the western coast  
of Leyte island (Fig. 3a). The sites consist of rocky patches of coral reef separated  
by sand flats (Fig. 3b). On the north edge, the sites are isolated from nearby habitat  
183 with no substantial reef habitat for at least 20 km.

Since 2012, we have sampled fish and habitat at most of the sites annually (Table  
A2). During sampling, divers using SCUBA and tethered to GPS readers swam the  
186 extent of each site. Divers visited each anemone inhabited by yellowtail clownfish  
and tagged anemones. At each anemone, the divers attempted to catch all of the  
yellowtail clownfish 3.5 cm and larger, took a small tail fin-clip from each for use in  
189 genetic analysis, measured the fork length, and noted the tail color (as an indicator of  
life stage). Starting in the 2015 field season, fish 6.0 cm and larger were also tagged

with a passive integrated transponder (PIT) tag, unless already tagged. Divers also  
192 looked for eggs around each anemone and measured and photographed any clutches found. In total, we took fin clips from and genotyped 2772 fish and PIT-tagged 1929 fish across all years and sites combined, marking 3413 individual fish.

195 **Estimating demographic and dispersal parameters from empirical data**

### Parentage analysis and dispersal kernel

198 We use a distance-based dispersal kernel fit from parent-offspring matches ((Catalano et al., in prep)), where the relative dispersal is a function of distance  $d$  in kilometers and parameters  $\theta = 1.19$  and  $z = e^{k_d=-2.33}$  that control the shape and scale of the  
201 kernel. The dispersal kernel is estimated using fish that have already recruited to a population and survived to be sampled so includes only the probability of dispersing, not pre-settlement mortality. To find the probability of fish dispersing among our  
204 sites, we numerically integrate the dispersal kernel using the distance from the middle of the origin site ( $i$ ) to the closest ( $d_1$ ) and farthest ( $d_2$ ) bounds of the destination site ( $j$ ):

$$p_{i,j}(d) = \int_{d_1}^{d_2} z e^{-(zd)^\theta} dd. \quad (4)$$

207 To account for uncertainty in the dispersal kernel, we use sets of the shape parameter  $\theta$  and the scale parameter  $k_d$  that represent the span of the 95% confidence interval.

210 **Growth and survival: mark-recapture analyses**

We marked fish with both genetic samples and PIT tags, allowing us to estimate growth and survival through mark-recapture. In total, we have 3413 marked fish  
213 with size and stage data for each capture time.

For growth, we estimate the parameters of a von Bertalanffy growth curve (Fabens, 1965) in the growth increment form relating the length at first capture  $L_t$  to the  
216 length at a later capture  $L_{t+1}$  (Hart and Chute, 2009), where  $L_\infty$  is the average asymptotic size across the population and  $K$  controls the rate of growth:

$$\begin{aligned} L_{t+1} &= L_t + (L_\infty - L_t)[1 - e^{(-K)}] \\ &= e^{(-K)}L_t + L_\infty[1 - e^{(-K)}]. \end{aligned} \tag{5}$$

We see from eqn. 5 that we would expect the first length  $L_t$  and the second length  
219  $L_{t+1}$  to be related linearly (Hart and Chute, 2009). From the slope  $m = e^{(-K)}$  and y-intercept  $b = L_\infty[1 - e^{(-K)}]$ , we calculate the von Bertalanffy parameters, such that  $K = -\ln m$  and  $L_\infty = \frac{b}{(1-m)}$ . We used the first and second capture lengths  
222 for fish that were recaptured after a year (within 345 to 385 days) to estimate  $L_\infty$  and  $K$ . We have some fish that were recaptured more than two times so we randomly selected only one pair of recaptures from each to use in estimating the parameters,  
225 then repeated this process 1000 times to generate a set of von Bertalanffy growth curves.

We use the full set of marked fish to estimate annual survival  $\phi$  and probability

228 of recapture  $p_r$  using the mark-recapture program MARK implemented in R (Laake,  
 2013). We fit several models with year, size, and site effects on the probability of  
 survival on a log-odds scale (see full list in Table A3). For fish that are not recaptured  
 231 in particular year, we estimate their size using our growth model (eqn. 5) and the  
 size recorded or estimated in the previous year. Because fish are not well-mixed at  
 our sites and instead stay quite close to their home anemones, we need to swim near  
 234 an anemone to have a reasonable chance of capturing the fish on it. Therefore, we  
 also consider a distance effect on recapture probability; we use the GPS tracks of  
 divers to estimate the minimum distance between a diver and the anemone for each  
 237 tagged fish in each sample year and include it as a factor in some of the models. We  
 compared the fit of the models using AICc and selected the model with the lowest  
 AICc value. (Table A3). ELABORATE ON AICc!!

## 240 **Fecundity**

We use a size-dependent fecundity relationship determined using photos of egg clutches  
 and females (Yawdoszyn, in prep), where the number of eggs per clutch ( $E_c$ ) is ex-  
 243 ponentially related to the length in cm of the female ( $L$ ) with size effect  $\beta_l = 2.388$ ,  
 intercept  $b = 1.174$ , and egg age effect  $\beta_e = -0.6083$  dependent on if the eggs are  
 old enough to have visible eyes. We multiply the number of eyed eggs per clutch by  
 246 the number of clutches per year  $c_e = 11.9$  (estimate from Holtswarth et al., 2017) to  
 get total annual fecundity  $f$ :

$$f = c_e * e^{\beta_l \ln(L) + \beta_e [\text{eyed}] + b}. \quad (6)$$

## Lifetime egg production

We use an integral projection model (IPM) (e.g. Rees et al., 2014) with size as the continuous structuring trait  $z$  to estimate lifetime egg production (LEP), the total number of eggs produced by one recruit. We initialize the IPM with one recruit-sized individual ( $\text{size}_{\text{recruit}}$ ) at the initial annual time step ( $t = 0$ ), then project forward for 100 time steps using the size-dependent survival (eqn. 11) and growth (eqn. 5) functions as the probability density functions that make up the kernel to describe the survival and growth of the individual into the next time step. This gives us the size distribution at each time step, which represents the probability that the individual has survived and grown into each of the possible size categories, ranging from a minimum of  $L_s = 0$  cm to a maximum of  $U_s = 15$  cm divided into 100 bins. The probability that the individual is still alive and of any size decreases as the time steps progress; by using a large number of steps, we are able to avoid arbitrarily setting a maximum age and instead let the probabilities become essentially zero.

We then multiply the size-distribution  $v_z$  at each time by the size-dependent fecundity  $f_z$  described above (eqn. 6) to get the total number of eggs produced at each time step. We then integrate across time and size to get the total number of eggs one individual is likely to produce in its lifetime:

$$\text{LEP} = \int_{t=0}^{100} \int_{z=L_s}^{z=U_s} v_{z,t} f_z dz dt. \quad (7)$$

To compute LEP, we discretize time and size and sum across the matrix. When entering the starting individual into the matrix, we use 0.1 as the standard deviation

of size ( $\text{size}_{\text{recruit},sd}$ ) and estimate the standard deviation of the distribution of sizes of fish in the next year ( $\text{size}_{sd}$ ) from our recapture data (A1).

We only consider reproductive effort once the fish has reached the female stage and use the average size of first observation as female for recaptured fish as the transition size  $L_f = 9.32\text{cm}$ . To incorporate uncertainty, we sample directly from the sizes at which recaptured fish were first captured as female (5.2 cm - 12.7 cm) (Fig. 4d).

### Survival from egg to recruit

We estimate survival from egg to recruit ( $S_e$ ) using parentage matches to estimate the number of surviving recruits produced by genotyped parents (similar to the method in Johnson et al., 2018). We scale the number of offspring we match back to parents ( $R_m = 62$ ) by various ways we could have missed offspring ( $P_h$ ,  $P_c$ ,  $P_d$ , and  $P_s$ , described below), then divide by the estimated number of eggs produced by genotyped parents, found by multiplying the number of genotyped parents ( $N_g = 1719$ ) by the expected lifetime egg production for a fish of parent size ( $\text{LEP}_p$ ):

$$S_e = \frac{\frac{R_m}{P_h P_c P_d P_s}}{N_g \text{LEP}_p}. \quad (8)$$

We scale the number of matched recruits we find by the cumulative proportion of habitat in our sites we sampled over time ( $P_h = 0.41$ , details in A.1), the probability of capturing a fish if we sampled its anemone ( $P_c = 0.56$ , see A.2 for details), and the proportion of the total dispersal kernel area from each our of sites covered within

our sampling region ( $P_d = 0.57$ , calculation in A.2). Finally, because our dispersal  
288 kernel gives the probability of dispersal given that a recruit settled somewhere but our sampling region is not all habitat, we scale by the proportion habitat in our sampling region ( $P_s = 0.20$ , details in A.2.0.1) to avoid counting this mortality twice.

291 To estimate  $\text{LRP}_{\text{local}}$ , we scale only by the proportion of habitat we cumulatively sample in our sites and the probability of capturing a fish.

To incorporate uncertainty in our estimate of egg-recruit survival, we consider  
294 uncertainty in the number of offspring assigned to parents during the parentage analysis ( $R_m$ ) and in the probability of capturing a fish ( $P_c$ ). We generate a set of values for the number of assigned offspring using a random binomial, where the  
297 number of trials is the number of genotyped offspring (745) and the probability of success on each trial is the assignment rate of offspring from the parentage analysis (0.079) (Catalano et al., in prep). For the probability of capturing a fish, we pull  
300 values from a beta distribution that captures the mean and variance of capture probabilities across recapture dives (details in A.2).

### Defining recruit and census stage

303 When assessing persistence, it is important to consider mortality and reproduction that occurs across the entire life cycle to determine whether an individual is replacing itself with an individual that reaches the same life stage (Burgess et al., 2014). We  
306 define a recruit to be a juvenile individual that has settled on the reef within the previous year, which also encompasses the size we are first able to sample (3.5-6.0 cm for parentage studies) (Fig. 2). In theory, it does not matter how we define recruit

<sup>309</sup> as long as we use that definition in our calculations of both egg-recruit survival and LEP. In our system, however, while it is straightforward to calculate LEP from any size, we do not have enough tagged recruits to reliably estimate survival to different recruit sizes. Instead, we choose the mean size of offspring matched in the parentage study as our best estimate of the size of a recruit ( $\text{size}_{\text{recruit}}$ ) and test sensitivity to different recruit sizes by pulling from a uniform distribution over the sizes the recruit <sup>312</sup> stage covers (3.5-6 cm, Table A1).  
<sup>315</sup>

### Accounting for density-dependence

Ideally we would assess persistence metrics when the population is at low abundance <sup>318</sup> and not limited by density-dependence. Clownfish have strong social hierarchies and juveniles on an anemone will prevent others from settling there as well (seen in *A. percula*, Buston, 2003a). Each anenome, therefore, can only house one settling clownfish, with anemones already occupied by *A. clarkii* settlers essentially unavailable as habitat. We attempt to account for this density-dependent mortality by multiplying <sup>321</sup> our estimate of settling recruits (the numerator of eqn. 8) by the proportional increase (DD) in unoccupied anemones at our sites if all of the *A. clarkii* anemones were unoccupied, where  $p_A$  is the proportion of anemones occupied by *A. clarkii* and  $p_U$  is the proportion of unoccupied anemones:  $DD = \frac{(p_U + p_A)}{p_U}$ . We present results <sup>324</sup> both with and without this density-dependence modification.  
<sup>327</sup>

### Estimated abundance over time

We also consider trends in abundance of breeding females at each site over time to  
330 compare to our replacement-based estimates of persistence. Similarly to as we do for  
offspring, we scale up the number of females caught at each site  $i$  in each sampling  
year  $t$  by the proportion of habitat sampled in that site and year  $P_{h_i,t}$  and by the  
333 probability of capturing a fish  $P_c$ :

$$\# \text{ females}_{i,t} = \frac{\# \text{ females captured}_{i,t}}{P_{h_i,t} P_c}. \quad (9)$$

We then fit a linear model through the time series for each site  $i$  sampled in at  
least three years to assess whether the slope over time is positive or negative:

$$\# \text{ females}_i \sim \text{year} \quad (10)$$

## Results

Our estimated abundance of females at each site over time does not suggest a clear  
trend (Fig. 1). In our very simple look at whether abundance seems to be increasing  
339 or decreasing, eleven sites had a positive slope over time and five had a negative  
slope (Fig. 1q). For the two largest sites, with a mean estimated number of females  
of between 150-200, one has a positive slope (Wangag, Fig. 1b) and one has a negative  
342 slope (Sitio Baybayon, Fig. 1p) and the next two largest sites are also split (Palanas,  
Fig. 1a and Haina, Fig. 1o). Overall, there is not a clear directional change in

abundance across the sites we sample over our sampling period.

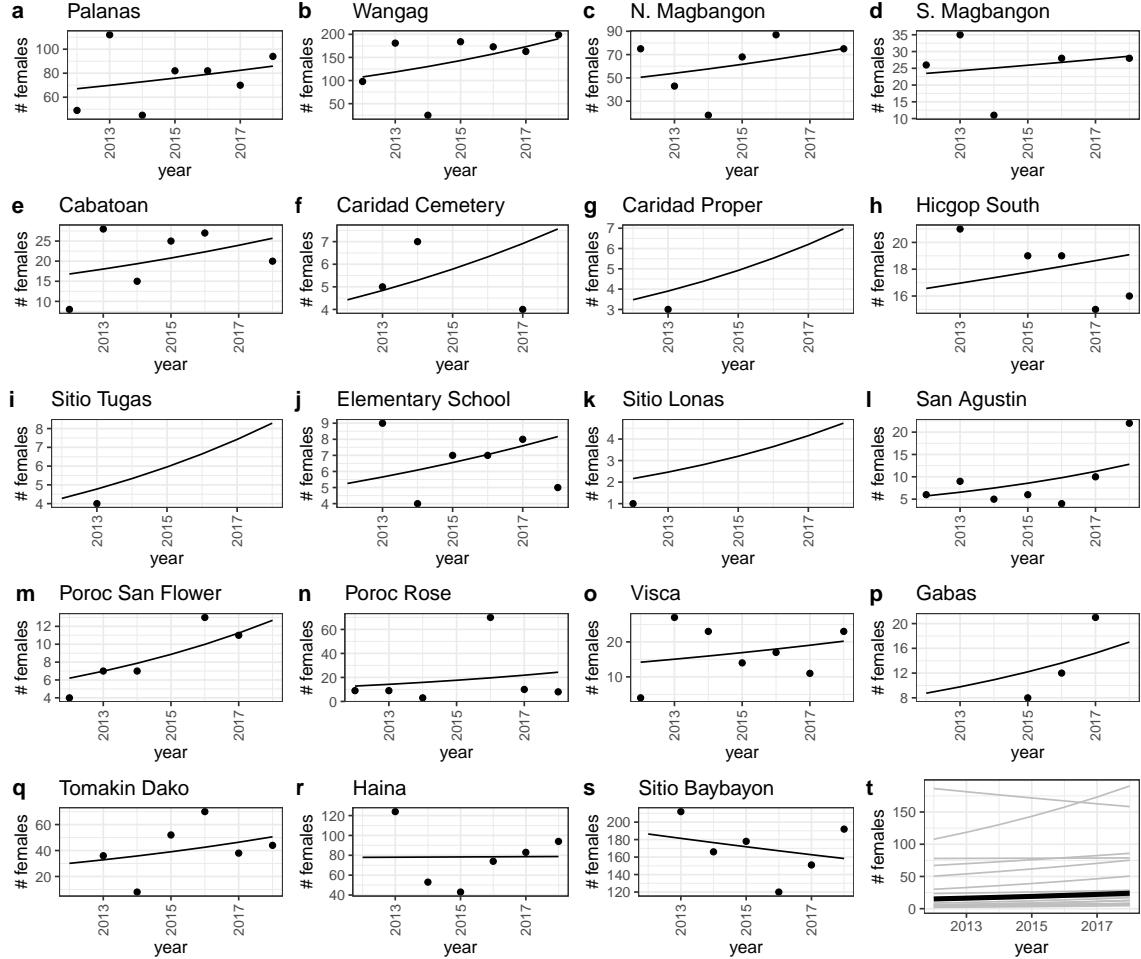

Figure 1: The estimated number of females at each site over the sampling years for sites sampled in at least three years. The total number of females at each site was estimated by scaling up the number of females captured at each site in each year by the proportion of habitat sampled at that site that season (see A.1 for details) and by the average probability of capturing a fish (see A.2). We show the estimated abundances and trend for each site individually (a-p) and a histogram of the slopes of abundance through time (q).

values of  $L_\infty = 10.71\text{cm}$  (range of estimates 10.50 - 10.90 cm) and  $K = 0.864$  (range of estimates 0.785 - 0.944) for the von Bertalanffy growth curve parameters (eqn. 5, Fig. 4b, Table A1). For juvenile and adult (post-recruitment) survival on a log-odds scale, the best-fit model has an effect of size, with coefficient  $b_a = 0.169 \pm 0.028$  SE and intercept  $b_\phi = -1.83 \pm 0.231$  SE (eqn. 11). The accompanying best-fit model for log-odds recapture probability has a negative size effect and a negative effect of diver distance from the anemone (eqn. A.3, Fig. A.4).

$$\log\left(\frac{\phi}{1-\phi}\right) = b_\phi + b_a \text{size.} \quad (11)$$

Using our best estimates for growth, survival, and fecundity, we calculate a value for LEP of 1061, ranging from 39 to 10345 when we consider uncertainty in the inputs (Fig. 5b). Adult survival has the most effect on the value of LEP (Fig. B.7), with higher values of LEP the higher annual survival of adults.

We estimate egg-recruit survival  $S_e$  to be 7.8e-04, ranging from 1.2e-04 to 0.033 when we include uncertainty in the number of offspring assigned to parents and the probability of catching a fish (APPENDIX FIG!). When we compensate for density-dependence in our data, we estimate  $S_e$  to be 0.0013, ranging from 2.1e-04 to 0.057. These are somewhat high values of egg-recruit survival compared to what we see elsewhere in the literature (e.g. Rumrill, 1990; Metaxas and Saunders, 2009) (though not unreasonable, e.g. White et al., 2014; Johnson et al., 2018) because we scale up by the amount of habitat in our sampling area and count mortality due to dispersal to non-habitat in the dispersal probability, rather than in  $S_e$ . Uncertainty in the size

<sup>366</sup> of transition to breeding female  $L_f$  has the largest effect on egg-recruit survival (Fig. B.9); we only consider reproduction from females, to avoid double-counting, so the larger the transition size to female, the fewer tagged eggs we estimate were produced  
<sup>369</sup> by genotyped parents and the higher egg-recruit survival.

We estimate lifetime recruit production (LRP), the product of LEP and  $S_e$ , to be 0.83, with a range of 0.28 - 3.89 when we consider uncertainty in inputs. When  
<sup>372</sup> we compensate for density-dependence, we estimate a value of 1.42 for LRP, with a range of 0.48 - 6.66. The value when we compensate for density-dependence and the range of uncertainty for both are above the threshold of one necessary for replacement  
<sup>375</sup> before considering dispersal. This mean that individuals at our sites produce enough surviving offspring before considering dispersal to be able to replace themselves, but LRP does not tell us whether those offspring will settle within our sample sites and  
<sup>378</sup> drive persistence.

We also estimate replacement for recruits from our sites returning to our sites, LRP<sub>local</sub>, which implicitly includes dispersal mortality, to be 0.09 (ranging from 0.03  
<sup>381</sup> to 0.44 when we include uncertainty) or 0.16 (0.05 to 0.76) when we compensate for density-dependence. With a value well below one, this suggests individuals at our sites do not replace themselves with recruits that settle in our sites, suggesting our  
<sup>384</sup> sites do not persist as an independent network. When we calculate LRP<sub>local</sub> using all arriving recruits to our sites, however, rather than just those originating there, the best estimates are  $> 1$  whether or not we compensate for density dependence (2.06,  
<sup>387</sup> 1.22, respectively), suggesting that there is recruit-recruit replacement at our sites when we include immigrant recruits.

We do not find any sites with  $SP > 1$ , whether we compensate for density-dependence or not (Fig. 6a), indicating that no site could persist in isolation. Given that our best estimate of LRP does not suggest replacement and only a fraction of those offspring stay at the natal site, this makes sense. We see the highest values of self-persistence at Haina ( $SP = 0.079, 0.13$  when compensating for density-dependence) and Wangag ( $SP = 0.048, 0.082$  when compensating for density-dependence), our two widest sites.

For network persistence, our best estimate of the dominant eigenvalue of the realized connectivity matrix  $\lambda_c$  is 0.21 with a range of 0.07 - 0.92 (Fig. 6), or 0.36 with a range 0.12 - 1.58 when we compensate for density-dependence (Fig. 6). Our sites are likely not network persistent, as our best estimates and most of the values we see in our runs with uncertainty are below one, but network persistence is possible, as our range of estimates does exceed one when we compensate for density-dependence. We see that most of the connectivity occurs among the sites in the northern part of our sample area, from Palanas to Caridad Cemetery, and at the southern part of our sample area from Tomakin Dako to Sitio Baybayon (Fig. 6b, d), where the largest sites are.

Based on our estimates of LRP,  $LRP_{local}$ , SP, and NP, it is possible but not likely that our set of sites is able to persist in isolation as a closed system. With our site configuration and dispersal kernel estimate, we would need a value of LRP of 3.99 (an egg-recruit survival of 0.0038 with our estimated value of LEP or a value of LEP of 5095 or 2975 with our estimated egg-recruit survival compensating and not compensating for density-dependence, respectively), to have a best estimate of

$\lambda_c = 1$  and network persistence.

## Discussion

414 We do not see strong evidence for persistence in our metric estimates. We see no  
evidence for self-persistence where an individual site could persist alone and weak  
evidence for network persistence; it is possible at the upper end of our range of esti-  
417 mates with uncertainty but not suggested by most of the range or our best estimates  
(Fig. 6). The abundances through time at our sites do not show a clear directional  
change, however, suggesting that the population at our sites is relatively constant  
420 but relies on input of recruits from outside sites to persist. The portion of coastline  
we sampled is likely a sink portion of a larger metapopulation.

For our sites to be able to persist as a network on their own, the number of  
423 surviving recruits produced by an average recruit - LRP - would likely need to be  
higher. With our estimated connectivity, LRP would need to be at least 3.99 to  
see network persistence among our sites, which is within the top of our range of  
426 uncertainty but about 3-5 times higher than our best estimates, without and with  
density-dependence compensation. Our best estimate of LRP when we compen-  
sate for density-dependence is greater than one, so higher connectivity and retention  
429 of offspring among our sites could lead to network persistence, but almost all sur-  
viving offspring would need to be retained. At our best estimate without density-  
dependence compensation, however, LRP is less than one - the average recruit only  
432 produces 0.83 of a surviving recruit of the same stage - so no amount of increased  
retention or connectivity, even retaining all of the recruits produced from our sites,

would lead to network persistence. Similarly, if other surrounding patch populations  
435 had a similar LRP, increasing the area of the network to include them would also not  
achieve network persistence. If nearby sites have higher egg production or survival to  
recruit, however, it might not take much of an increase in area considered to create  
438 a persistence network. Nearby reef sites such as Cuatro Islas have higher quality  
habitat and could be contributing recruits to our sites.

We do not find clear evidence for network persistence for our sites despite esti-  
441 mates of the mean dispersal distance of *A. clarkii* from previous genetic work (11  
km, Pinsky et al., 2010) and from our samples (8.25 km, with 95% confidence in-  
terval 7.41 to 9.36, Catalano et al., in prep) that are well within the 30 km span of  
444 our sites. Though the width of our sampling region is more than twice the mean  
dispersal distance, which Lockwood et al. (2002) find sufficient for persistence of an  
isolated reserve, their estimate assumes continuous habitat within the reserve and  
447 our region is only about 20% habitat. For a habitat configuration more similar to  
our system, habitat patches (reserves) spaced on a coastline with non-habitat in be-  
tween, they find that either 40% of the coastline needs to be preserved or a minimum  
450 patch size must be 1.25 times the mean dispersal distance to ensure persistence. Our  
largest site, Haina, is only about 0.8 km wide, about 10 times less than the mean  
dispersal distance, so it is possible we do not have enough habitat in our region for  
453 network persistence, exacerbated by our 4 largest sites being at the edges of our  
area and sending half of their recruits away from our sites. Our low, and possibly  
below-replacement, estimate for LRP also suggests that lack of persistence in these  
456 sites is not due to excessive dispersal out of the area but due to low production and

survival of offspring. The reef health and habitat quality in our sites is generally low, due anthropogenic effects such as pollution and silt from a nearby gravel mine,  
459 and habitat disturbance due to storms. Our sites are in an area that was hit in 2013 by Typhoon Haiyan, one of the strongest typhoons ever to make landfall, which destroyed much of the reef habitat in some of our northern sampling areas. This recent  
462 disturbance and generally low habitat quality could contribute to low production of surviving recruits in our sites (seen in other populations with low habitat quality, e.g. Hayashi et al., 2019) necessitating subsidization by outside populations.

465 We see considerable uncertainty in our estimate of persistence metrics depending on the particular input values we use (Figs. 5, B.10). Our highest estimate for LRP is about 24 times more than our lowest estimate and our highest NP estimate is  
468 about 22 larger than our lowest, spanning the range between network persistence for our set of sites to far from it. Measuring demographic and dispersal parameters in the field is challenging; in the face of limited and imperfect data, characterizing  
471 uncertainty and propagating it from our estimates of demographic and dispersal inputs through to our estimates of persistence metrics is important to contextualize our results. In our study, uncertainty in egg-recruit survival (a commonly challenging parameter to estimate, e.g. Johnson et al., 2018; Hameed et al., 2016), partially driven by uncertainty in how likely we are to capture recruits during sampling (Figs. B.9, ??), has a large effect on whether or not we think our populations are persistent.  
477 For a marine metapopulation, our system is relatively uncomplicated and yet still hard in which to concretely ascertain persistence. As we accumulate more empirical assessments of metapopulations to compare to our expectations from theory and

480 models, we will have to think carefully about how to handle uncertainty as we move  
to tackling larger and more complicated systems.

Persistence criteria, such as those detailed in Hastings and Botsford (2006a) and  
483 Burgess et al. (2014), ask whether a population at low abundance can grow and  
recover rather than going extinct. Density-dependence is often ignored at low abun-  
dances (e.g. Caswell, 2001; Hastings and Botsford, 2006b) so is not explicitly con-  
486 sidered in persistence metrics. In real populations, however, it can be challenging  
to estimate density-independent demographic rates, as density-dependence is occur-  
ring in the population as it is sampled. In *A. clarkii*, density-dependence is likely  
489 most important in early life stages, as for many fish species, but could play an im-  
portant role throughout the life history due to the social hierarchies in colonies of  
clownfish (e.g. Buston and Elith, 2011). In other species of clownfish, individuals  
492 on the same anemone maintain strict size spacing, restricting their food intake and  
growth to avoid encroaching on the position of another fish and being attacked or  
evicted (seen in *A. percula*, Buston, 2003a,b). This suggests that while fish are in  
495 the pre-reproductive queue, density-dependence may lower growth rates compared to  
the growth of fish alone on an anemone, as would be the case in a population at low  
abundance. We attempt to account for the primary effect of density-dependence on  
498 our estimate of egg-recruit survival but other estimates, particularly growth and sur-  
vival, would also likely be higher in the absence of density-dependence and increase  
LRP.

501 Our estimates of persistence metrics suggest that it is possible but not likely that  
the region of sites we sample persist as a network without outside input, despite

covering an area more than twice the estimated mean dispersal distance for our focal  
504 species. Our estimate of LRP near the threshold of one required for replacement  
(slightly  $< 1$  when we do not compensate for density-dependence, slightly  $> 1$  when  
we do), suggests that dispersal is not likely the primary reason our sites do not persist  
507 as a network. If density-dependence is strongly present in our data such that our  
compensated estimate is the best, then our sites could persist if there were no losses  
to dispersal. Otherwise, our sites do not produce enough offspring for replacement  
510 regardless of dispersal patterns, possibly due to worsening habitat quality. This is  
a reminder that dispersal is only part of the persistence story for metapopulations;  
even areas that seem large enough to contain a persistent network based on dispersal  
513 distance will not be able to persist in isolation if they have low production and  
survival of offspring. We do find recruits coming back to our region, and even to  
their natal site, but broader connectivity to more productive sites likely enables our  
516 sites to persist.

## Figures

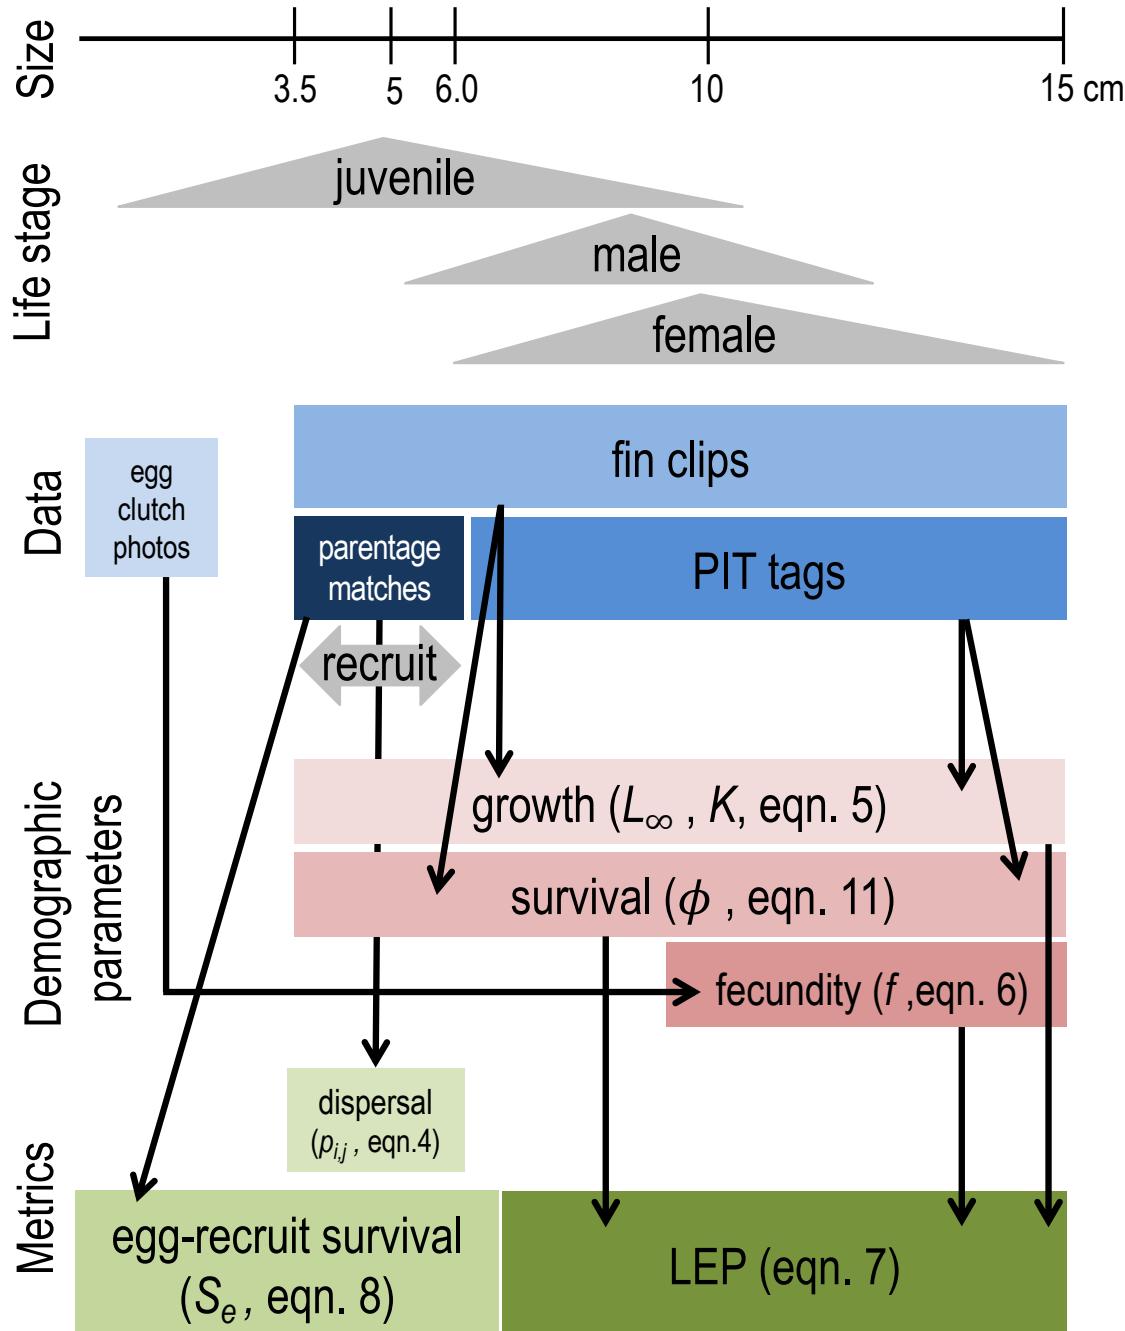

Figure 2: This schematic visualizes the data collected for fish at each life stage and how they match to the equations and metrics we estimate. We consider recruits to be offspring in their first year of settlement, represented by the 3.5-6.0 cm range. 28

All estimates include compensation for density-dependence in early life stages in our data. For self-persistence (a) and network persistence (c), the best estimate is shown with in black (point for (a), line for (c)) and the range of estimates considering uncertainty is shown in grey.

# Appendix

## <sup>519</sup> Summary of parameters

Parameter	Description	Best estimate	Range in uncertainty runs	Notes
$k_d$	scale parameter in dispersal kernel	-2.11	-2.36 to -1.96	estimated using methods in Bode et al. (2018) in Catalano et al. (in prep)
$\theta$	shape parameter in dispersal kernel	1	NA	estimated using methods in Bode et al. (2018) in Catalano et al. (in prep)
$L_\infty$	average asymptotic size in von Bertalanffy growth curve	10.70 cm	10.50 to 10.90 cm	

$K$	growth coefficient in von Bertalanffy growth curve	0.864	0.785 to 0.944	
$b_\phi$	intercept for adult survival	-1.82	$\pm 0.231$ standard error	on a log-odds scale
$b_a$	size effect for adult survival	0.169	$\pm 0.028$ standard error	on a log-odds scale
$b_{pr}$	intercept for recapture probability from mark-recapture analysis	2.10	$\pm 0.849$ standard error	on a log-odds scale, not used in persistence estimates
$b_1$	size effect for recapture	-0.161	$\pm 0.088$ standard error	on a log-odds scale, not used in persistence estimates
$b_2$	distance effect for recapture	-0.196	$\pm 0.023$ standard error	on a log-odds scale, not used in persistence estimates

size <sub>recruit</sub>	size (cm) of recruited offspring	mean of size of offspring in parentage analysis = 4.37 cm	3.5 - 6.0 cm	drawn from uniform distribution across range
size <sub>recruit, sd</sub>	standard deviation of size of a recruit	0.1		used in discretization of IPM for LEP
size <sub>sd</sub>	standard deviation distribution of sizes of a fish in the next year	1.45		used in discretization of IPM for LEP, estimated from range of sizes for fish starting at 7.4-7.6 cm and recaptured a year later
$b_e$	coefficient for eyed eggs	-0.608		Yawdoszyn et al. (in prep)
$b_l$	size effect in eggs-per-clutch relationship	2.39		Yawdoszyn et al. (in prep)
$b$	intercept in eggs-per-clutch relationship	1.17		Yawdoszyn et al. (in prep)

$c_e$	egg clutches per year	11.9		Holtswarth et al. (2017)
$L_f$	size at transition to female	9.32cm	5.2 - 12.7cm	drawn from distribution in data
$P_h$	proportion of sites sampled cumulatively across time	0.41		details in A.1
$P_d$	proportion of dispersal kernel area from each site covered by our sampling region	0.57		details in A.2
$P_c$	probability of capturing a fish	0.56	drawn from beta distribution with parameters $\alpha_{P_c} = 1.44$ and $\beta_{P_c} = 1.13$	details in A.2

$P_s$	proportion of our sampling region that is habitat	0.20		details in A.2.0.1
DD	proportion of habitat that would be available without density-dependence at settlement	1.71		
$p_U$	proportion of anemones unoccupied by clownfish	0.53		used to estimate DD
$p_A$	proportion of anemones occupied by <i>A. clarkii</i>	0.38		used to estimate DD
$L_s$	minimum size in LEP IPM	0		eqn. 7

$U_s$	maximum size in LEP IPM	15		eqn. 7
-------	----------------------------	----	--	--------

Table A1

## A Method details

### A.1 Proportion of habitat sampled

We used tagged anemones to estimate the proportion of habitat sampled at each site in each year ( $P_{h_{i,t}}$ ). We tagged each anemone that is home to *A. clarkii*, with a metal tag, which is relatively permanent and easy to re-sight (the anemone tag is visible above the anemone in Fig. 3c), so we consider the total number of metal tags at each site to be the total number of anemones that are habitat. We divide the number of tagged anemones visited each sampling year by the total number of metal tags at that site to get the proportion of habitat sampled. We use proportion of anemones rather than proportion of total site area because anemones, and therefore habitat quality, are unevenly distributed across the site; areas we did not visit are likely to have a lower density of anemones than the areas we did sample.

For scaling the number of tagged recruited offspring to account for areas of our sites we did not sample, we use the overall proportion habitat sampled across all sites and sampling years ( $P_h$ ). We sum the metal-tagged anemones we visited across all sites and years to get the total number of metal-tagged anemones we visited while sampling. We then divide that by the number of anemones we could have sampled,

Site	# Total anems	% Habitat surveyed						
		2012	2013	2014	2015	2016	2017	2018
Cabatoan	26	42	58	58	65	73	0	62
Caridad Cemetery	4	0	75	50	0	50	50	50
Elementary School	8	0	100	38	88	88	88	100
Gabas	9	0	0	0	44	44	67	0
Haina	104	0	6	13	13	10	56	80
Hicgop South	18	0	67	22	28	56	83	78
N. Magbangon	105	5	12	40	63	63	0	5
S. Magbangon	34	41	56	32	0	65	0	71
Palanas	137	29	58	47	63	85	86	86
Poroc Rose	13	100	100	69	31	23	69	69

Wangag	296	18	32	42	34	26	49	68

Table A2: Table showing the percent of metal-tagged anemones surveyed at each site in each sampling year.

537 the sum of total metal-tagged anemones across all sites multiplied by the number of sampling years, to get the overall proportion habitat sampled across our sites and sampling years.

540 **A.2 Probability of capturing a fish, from recapture dives**

We use mark-recapture data from recapture dives done within a sampling season to estimate the probability of capturing a fish. During some of the sampling years (XX), portions of the sites were sampled again XX-XX weeks after the original sampling dives. We assume there is no mortality of tagged fish between the original sampling dives and the recapture dives because they are so close in time and that fish do not change their behavior or response to divers, so therefore assume that the probability of recapturing a fish is the same as the probability of capturing a fish on a sample dive. For each recapture dive, we use GPS tracks of the divers to identify the anemones covered in the recapture dive and the set of PIT-tagged fish encountered on those anemones during the original sampling dives. We estimate the probability of capture  $P_c$  as the number of tagged fish caught during the capture dive  $m_2$  divided by the total number of fish caught on the recapture dive  $n_2$ :  $P_c = \frac{m_2}{n_2}$ .

We use the mean  $P_c$  across all 14 recapture dives, covering XX sites in 3 sampling seasons (2016, 2017, 2018), as our best estimate. Because there are so few recapture dives compared to the number of times we calculate the metrics to show the range of uncertainty, we represent the probability of capture as a distribution, rather than pulling directly from the values calculated for each recapture dive. The distribution of capture probabilities across the 14 dives is quite skewed so we represent it as a beta distribution, using the mean  $\mu_{P_c}$  and variance  $V_{P_c}$  of the set of 14 values to find the appropriate  $\alpha_{P_c}$  and  $\beta_{P_c}$  parameters, where

$$\alpha_{P_c} = \left( \frac{1 - \mu_{P_c}}{V_{P_c}} - \frac{1}{\mu_{P_c}} \right) \mu_{P_c}^2 \quad (\text{A.1})$$

$$\beta_{P_c} = \alpha_{\mu_{P_c}} \times \frac{1}{\mu_{P_c} - 1}. \quad (\text{A.2})$$

<sup>561</sup> The mean of the individual capture probability values is  $\mu_{P_c} = 0.56$ , with variance  
 $V_{P_c} = 0.069$ , which gives beta distribution parameters  $\alpha_{P_c} = 1.44$  and  $\beta_{P_c} = 1.13$ .  
<sup>562</sup> We sample 1000 values from the beta distribution, then truncate the sample to only  
<sup>563</sup> values larger than the lowest value of  $P_c$  estimated in an individual dive (0.20), to  
<sup>564</sup> avoid extremely low values that are sometimes sampled but are unrealistically low.  
<sup>565</sup> We then sample with replacement from the truncated set to get a vector of values  
<sup>566</sup> the length of the number of runs.

## Scaling up recruits

ADD SOME TEXT!

How could we have missed potential recruits originating from our sites?

- 1) Failed to catch recruit when sampling ( $P_c$ )
- 2) Missed sampling some habitat areas within our sites ( $P_h$ )
- 3) Recruit dispersed outside our study region ( $P_d$ )
- 4) Recruit dispersed to non-habitat within our region ( $P_s$ )
- 5) Recruit died due to density-dependent competition with other settlers (DD)

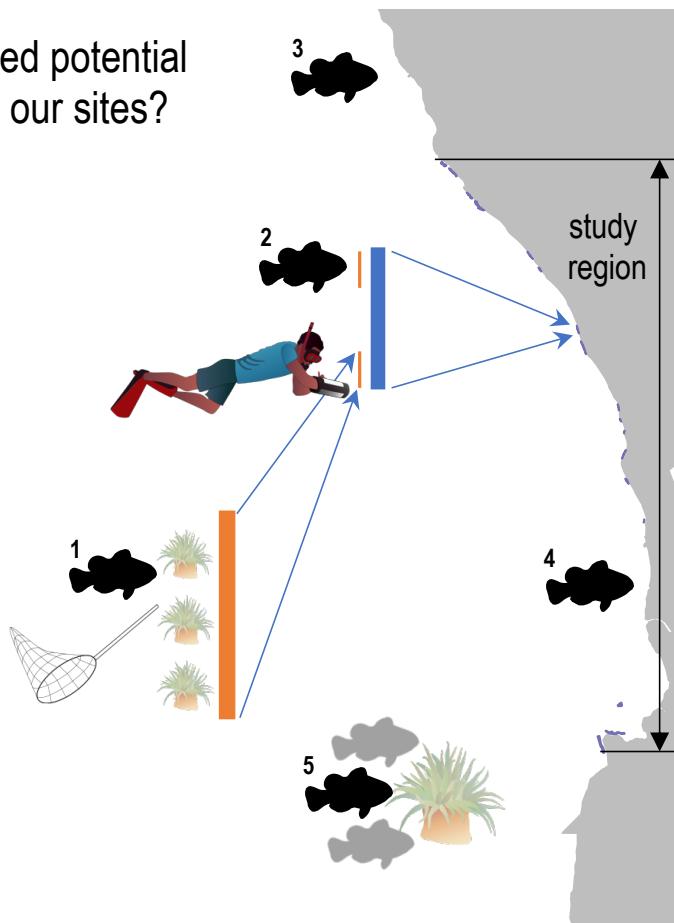

Figure A.1: Schematic of five ways we could have missed recruits while sampling and used to scale up our raw estimate of recruits from matched offspring.

<sup>570</sup> **Proportion of dispersal kernel area sampled**

[Add in description of calculation and equation]

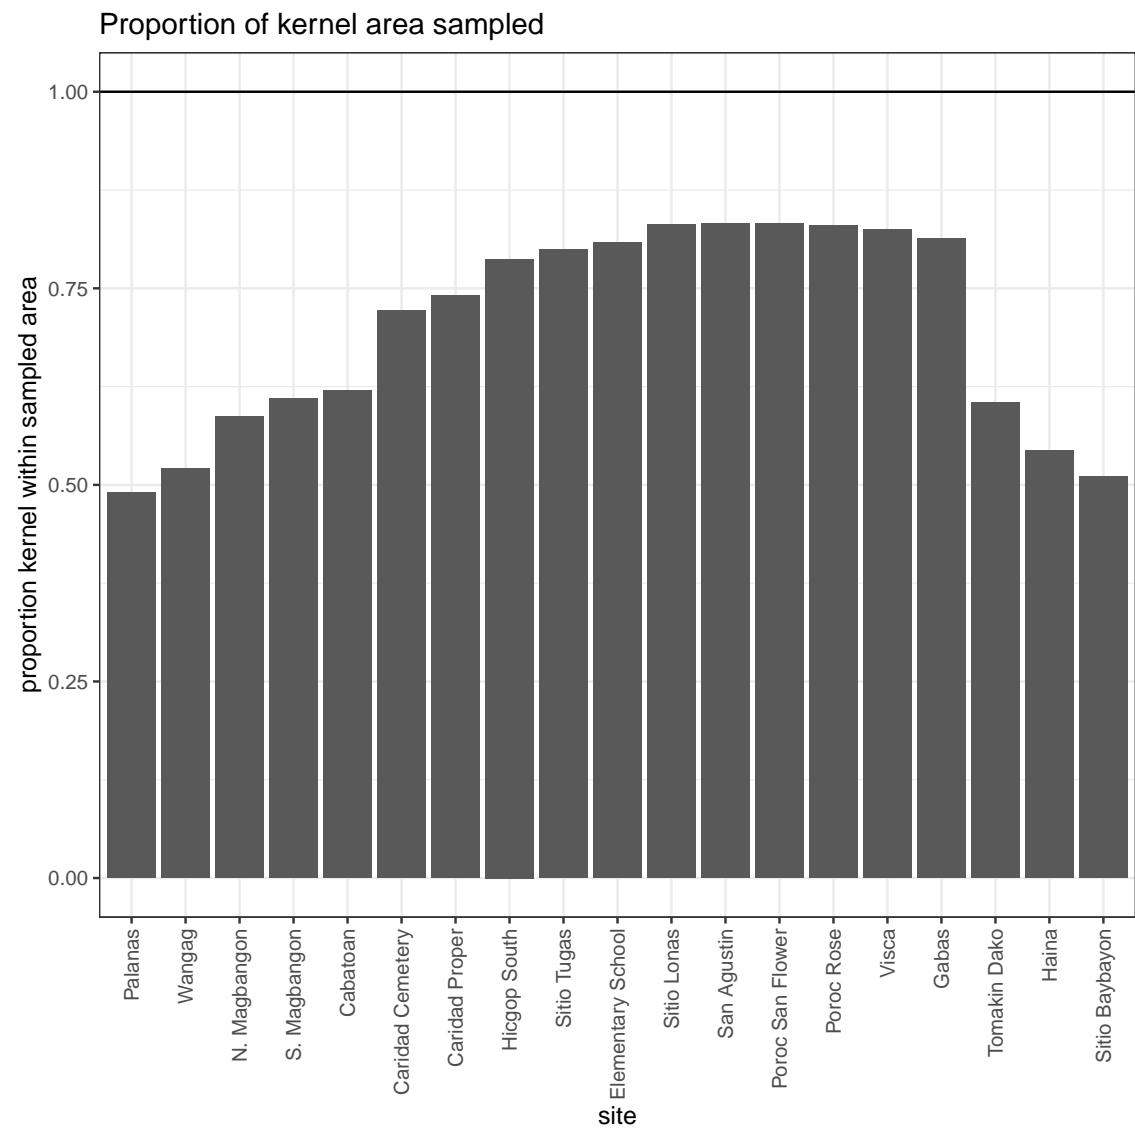

Figure A.2: Proportion of the dispersal kernel area from the center of each site covered by our sampling.

#### A.2.0.1 Proportion habitat in sampling area

573 We assume that larvae are unable to navigate to habitat if they attempt to settle  
on an unsuitable patch, though clownfish larvae do likely have some ability both to  
sense habitat (CITATIONS) and move toward it (CITATIONS)). To avoid counting  
576 mortality due to settling on non-habitat twice - once in scaling up our matched  
recruits, which only includes those who settled on habitat, and once in integrating  
the dispersal kernel, we scale our estimate of total surviving recruits from our patches  
579 by the proportion of our sampling region that is habitat ( $P_s$ ). We find  $P_s$  by summing  
the lengths of all of our sites, which run approximately north-south, and dividing  
that by the total distance north-south of our sampling region, giving  $P_s = 0.20$ .

Model	Model description	AICc	dAICc
$\phi \sim S, p \sim S + D$	survival size, recapture size+distance	3348.861	0
$\phi \sim S, p \sim D$	survival size, recapture distance	3359.998	-11.1371
$\phi, p \sim D$	survival constant, recapture distance	3383.175	34.3141
$\phi, p \sim S + D$	survival constant, recapture size+distance	3384.959	36.0981
$\phi \sim t, p$	survival time, recapture constant	3408.342	59.4816
$\phi \sim i, p$	survival site, recapture constant	3440.842	91.98112
$\phi \sim i, p \sim S + D$	survival site, recapture size+distance	3440.842	91.98112
$\phi, p \sim t$	survival constant, recapture time	3453.609	104.74839
$\phi \sim S, p \sim S$	survival size, recapture size	3527.710	178.84940
$\phi, p$	survival constant, recapture constant	3570.908	222.04690

Table A3

<sup>582</sup> **A.3 Full set of MARK models**

We consider the following set of models in MARK for survival ( $\phi$ ) and recapture ( $p$ ) probability, including effects of size ( $S$ ), minimum distance from diver to anemone during surveys ( $D$ ), time ( $t$ ), and site ( $i$ ) (Table A3):

The best model includes both site and size in survival

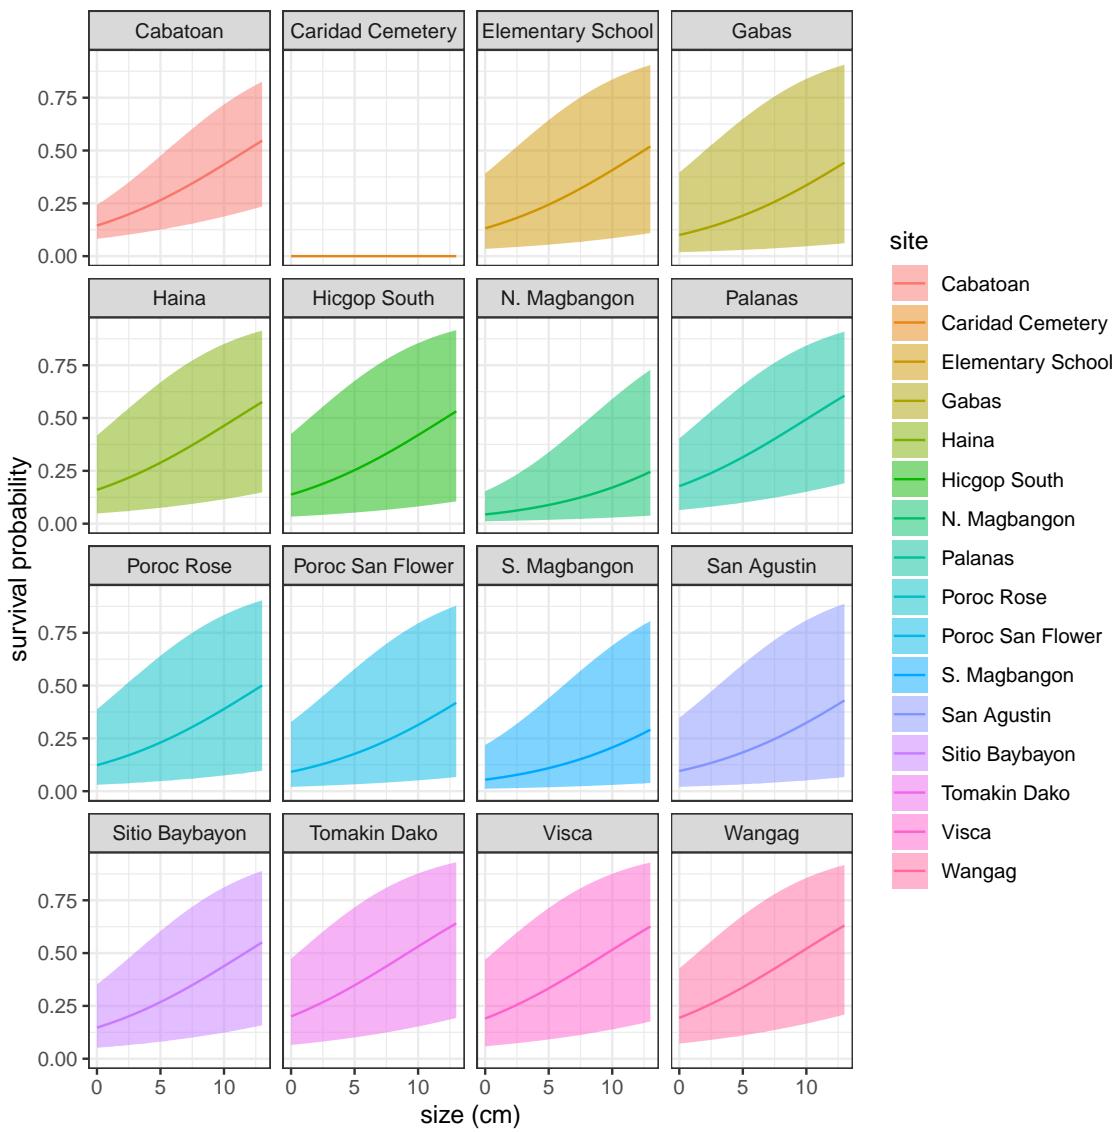

Figure A.3: Annual survival by size at each site.

#### A.3.0.1 Recapture model

<sup>588</sup> The best model for log-odds recapture probability, accompanying the survival model in eqn. 11, has a size effect ( $b_1 = -1.816 \pm 0.080$  SE, Fig. A.4a) and a negative

effect of diver distance from the anemone ( $b_2 = -0.171 \pm 0.021$  SE, Fig. A.4b), with  
 591 intercept  $b_{pr} = 17.93 \pm 0.858$  SE:

$$\log\left(\frac{p_r}{1 - p_r}\right) = b_{pr} + b_1 \text{size} + b_2 d. \quad (\text{A.3})$$

The negative effect of both size and distance suggest that divers are less likely to recapture larger fish and those at anemones far from areas sampled.

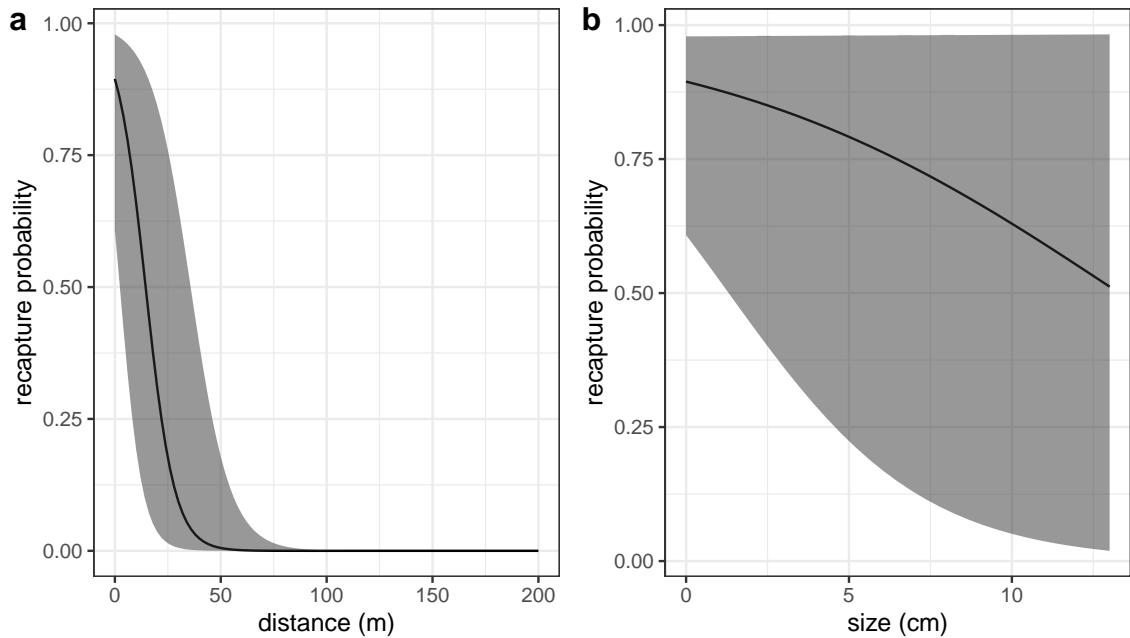

Figure A.4: Effects of a) minimum distance between divers and the anemone where the fish was first caught and b) fish size on the probability the fish will be recaptured, estimated along with survival in a mark-recapture analysis. Size has a slightly negative effect on the probability of recapture - larger fish are stronger swimmers and more likely to flee the anemone when divers approach, but with high uncertainty at larger sizes. Distance also has a negative effect on recapture, as fish tend to stay close to their anemones and are not likely to be recaptured if divers do not get close to their anemone.

## B Result details and sensitivity

### Abundance trends by site

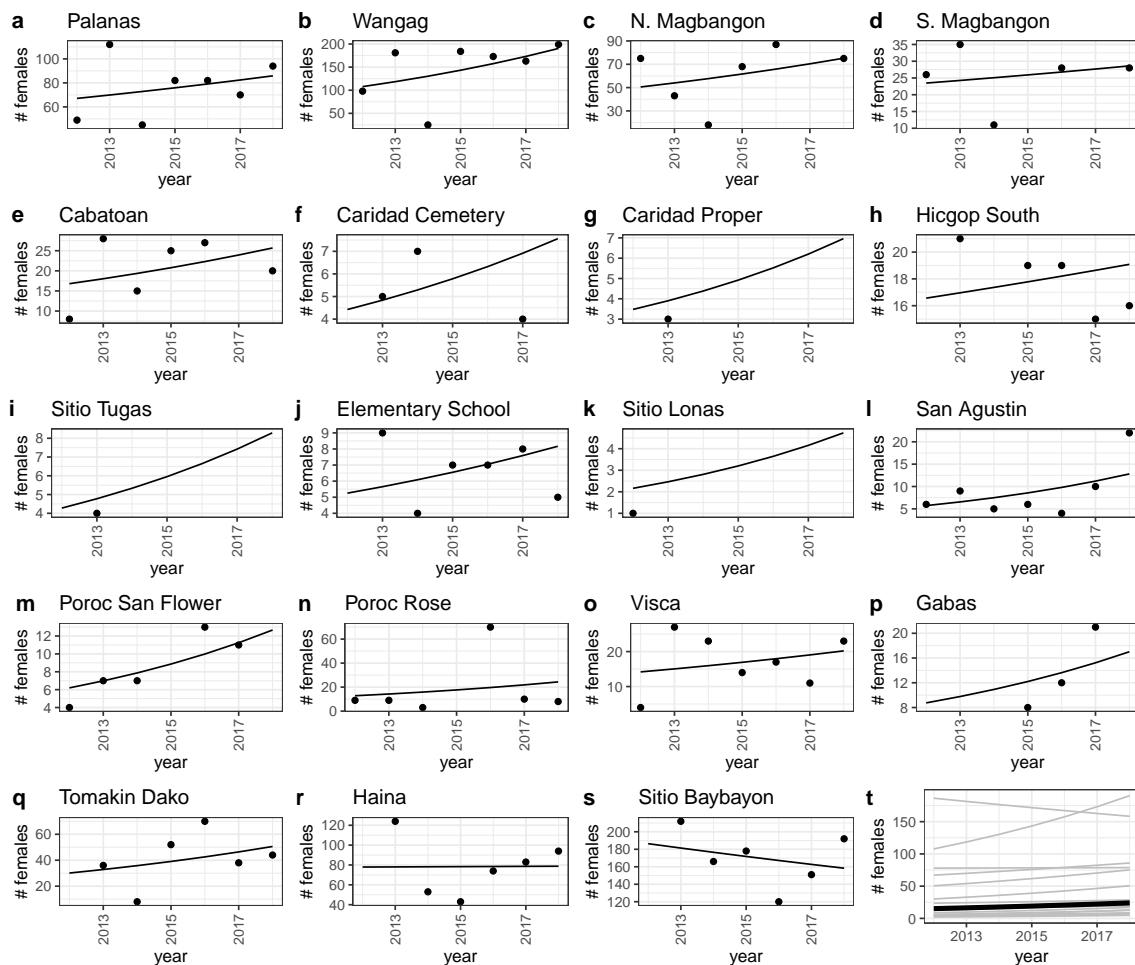

Figure B.1: Scaled estimates of females and abundance trends by site.

## **Compensating for density dependence**

597 TALK ABOUT HOW DENSITY DEPENDENCE AFFECTS OUR RESULTS, CITE SECTION OR EQUATION WHERE WE COMPENSATE FOR IT

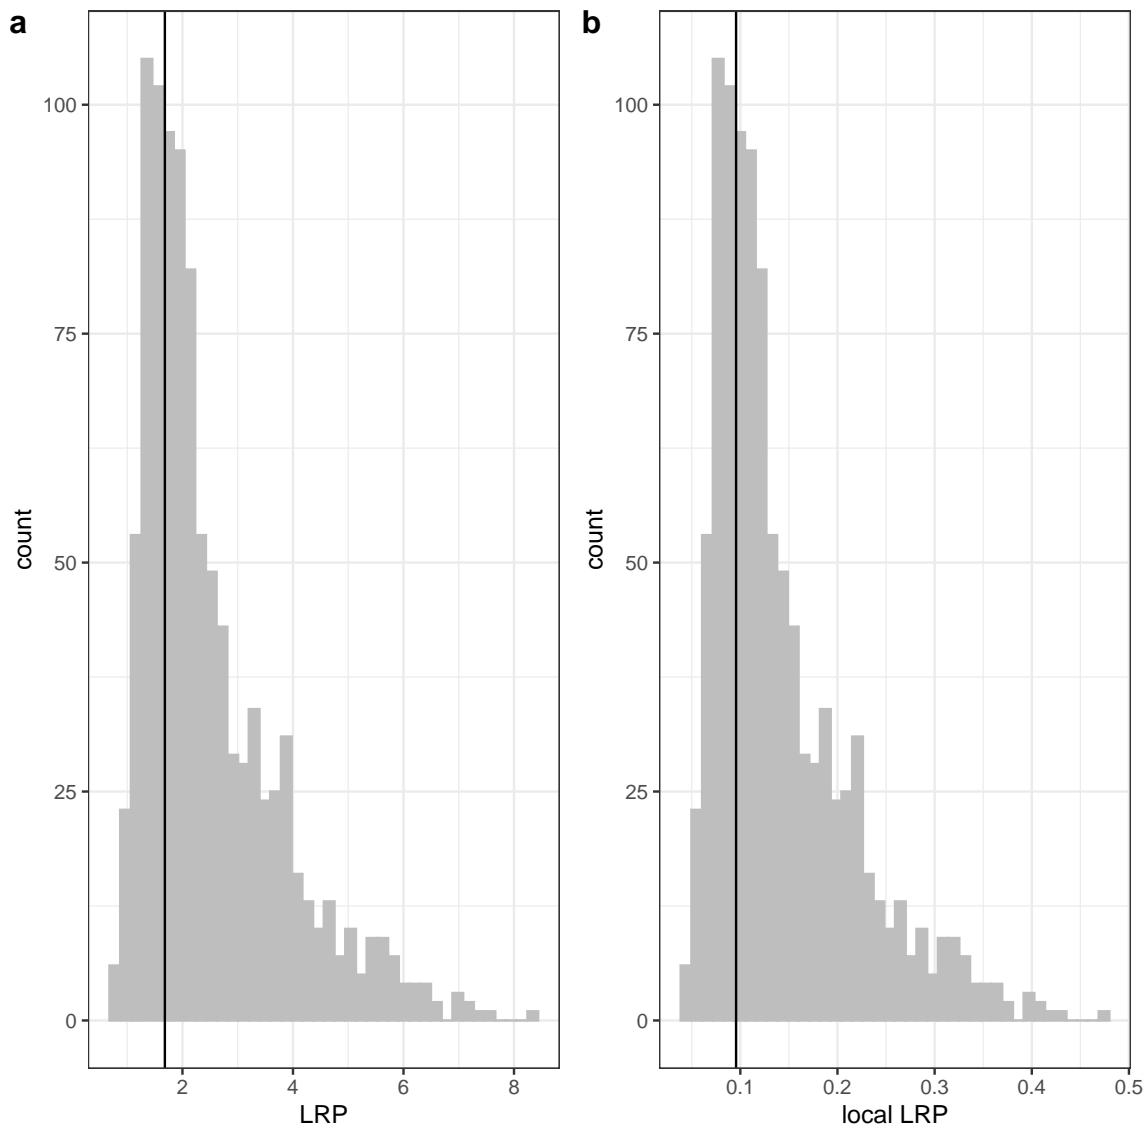

Figure B.2: Estimates of a) LRP, and b) local replacement without compensating for density dependence in early life stages in our data, showing the best estimate (black solid line) and range of estimates considering uncertainty in the inputs. These estimates compare to those in 5c,d, where we attempt to compensate for additional mortality in early life due to density dependence.

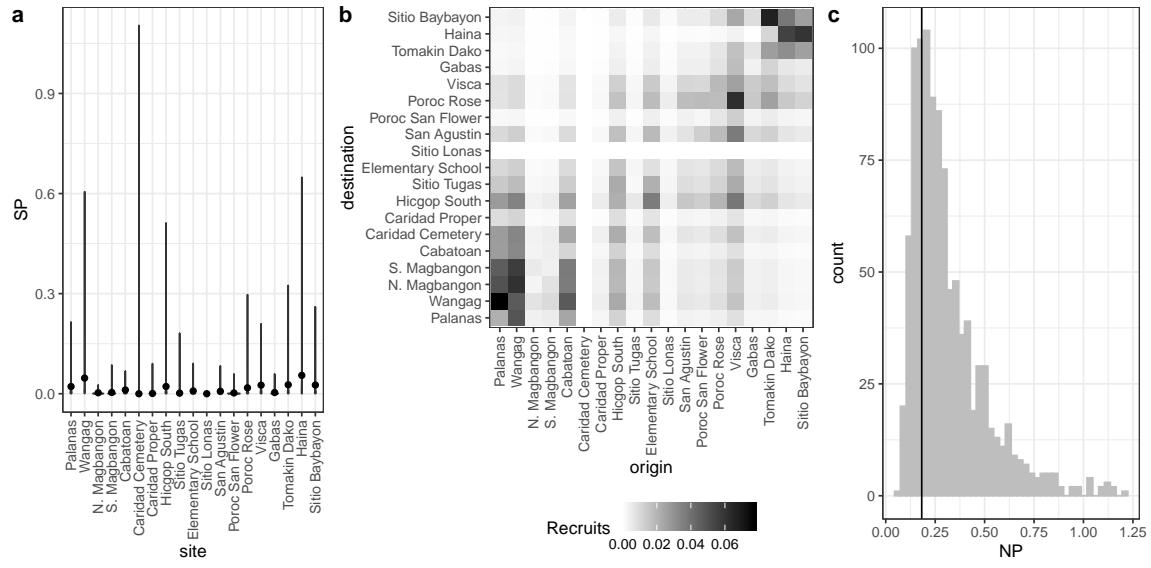

Figure B.3: Values of self-persistence (a), realized connectivity among sites (b), and network persistence (c) without compensation for density-dependence in early life stages in our data. For self-persistence (a) and network persistence (c), the best estimate is shown with in black (point for (a), line for (c)) and the range of estimates considering uncertainty is shown in grey. These estimates compare to those in 6 where we attempt to compensate for density dependence in early life stages.

## LEP and LRP by site

600 WRITE SOME TEXT!

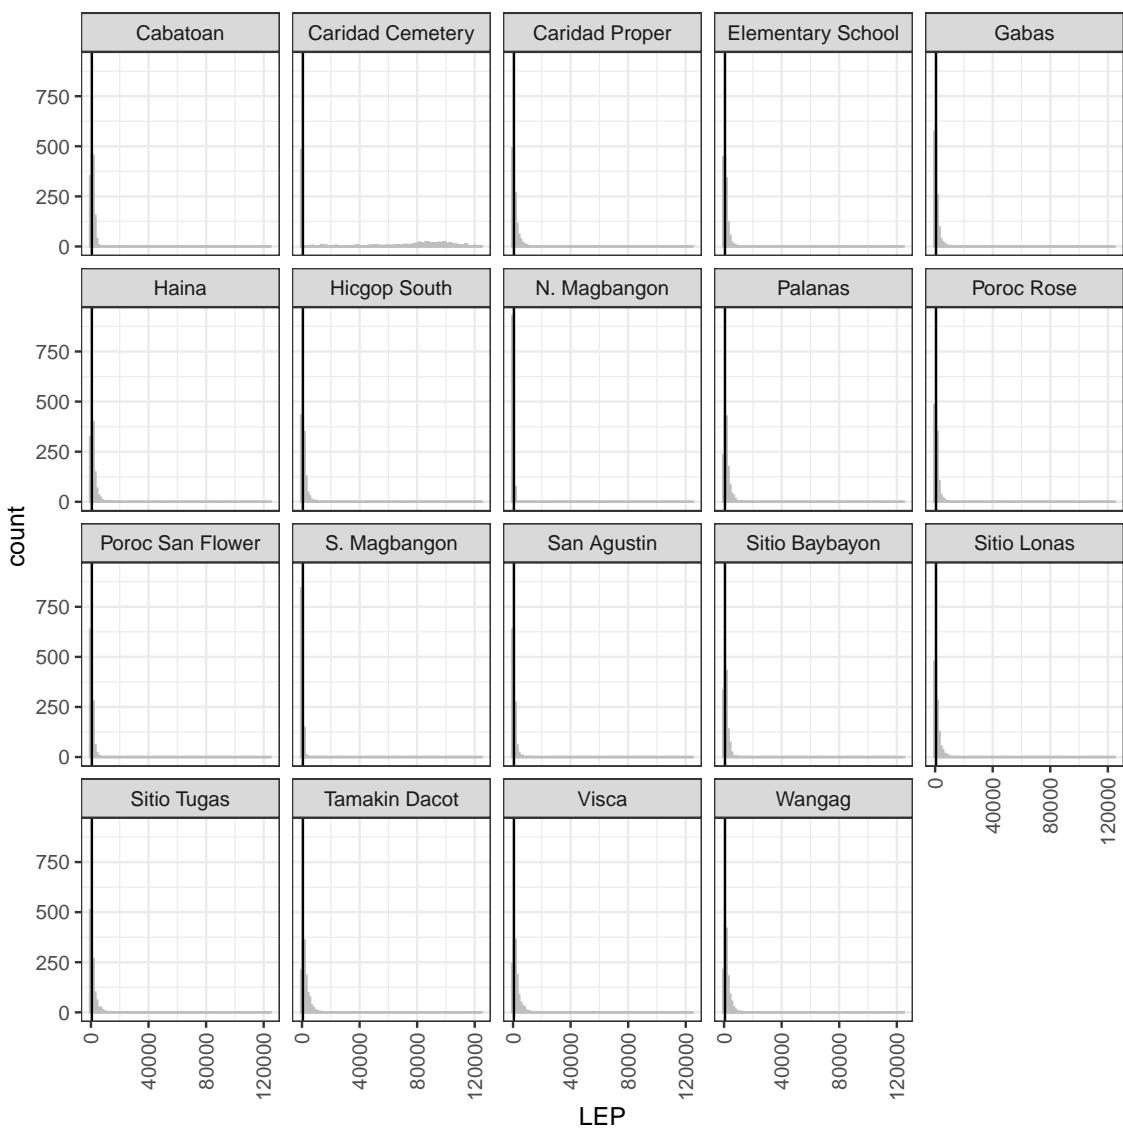

Figure B.4: Write a caption.

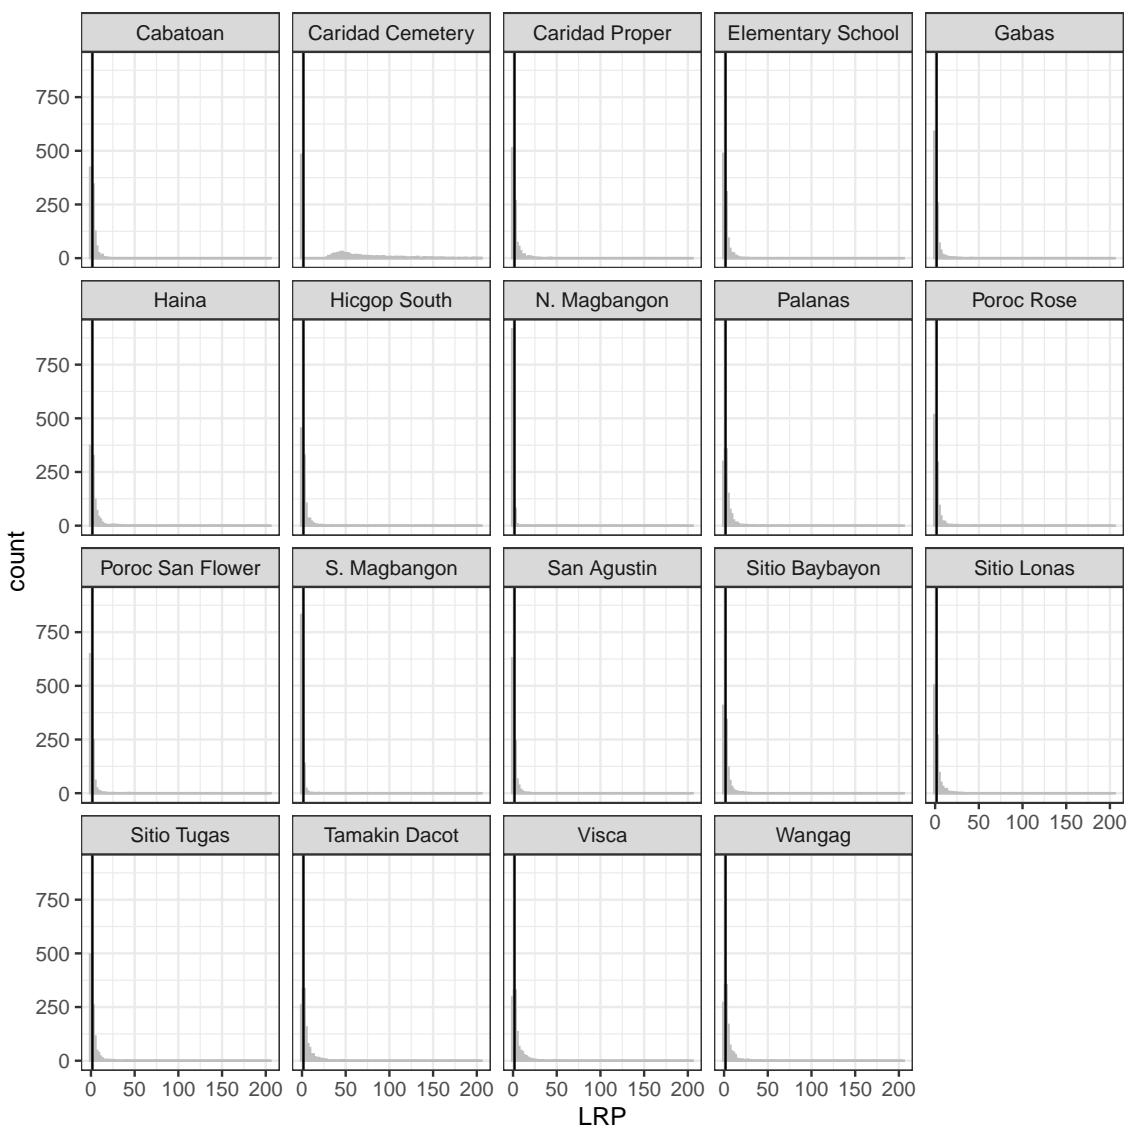

Figure B.5: Write a caption.

## B.1 Sensitivity to parameters

EXPLAIN THAT THESE ARE THE REST OF THE PARAMETERS, NOT SHOWN

603 IN THE MAIN TEXT

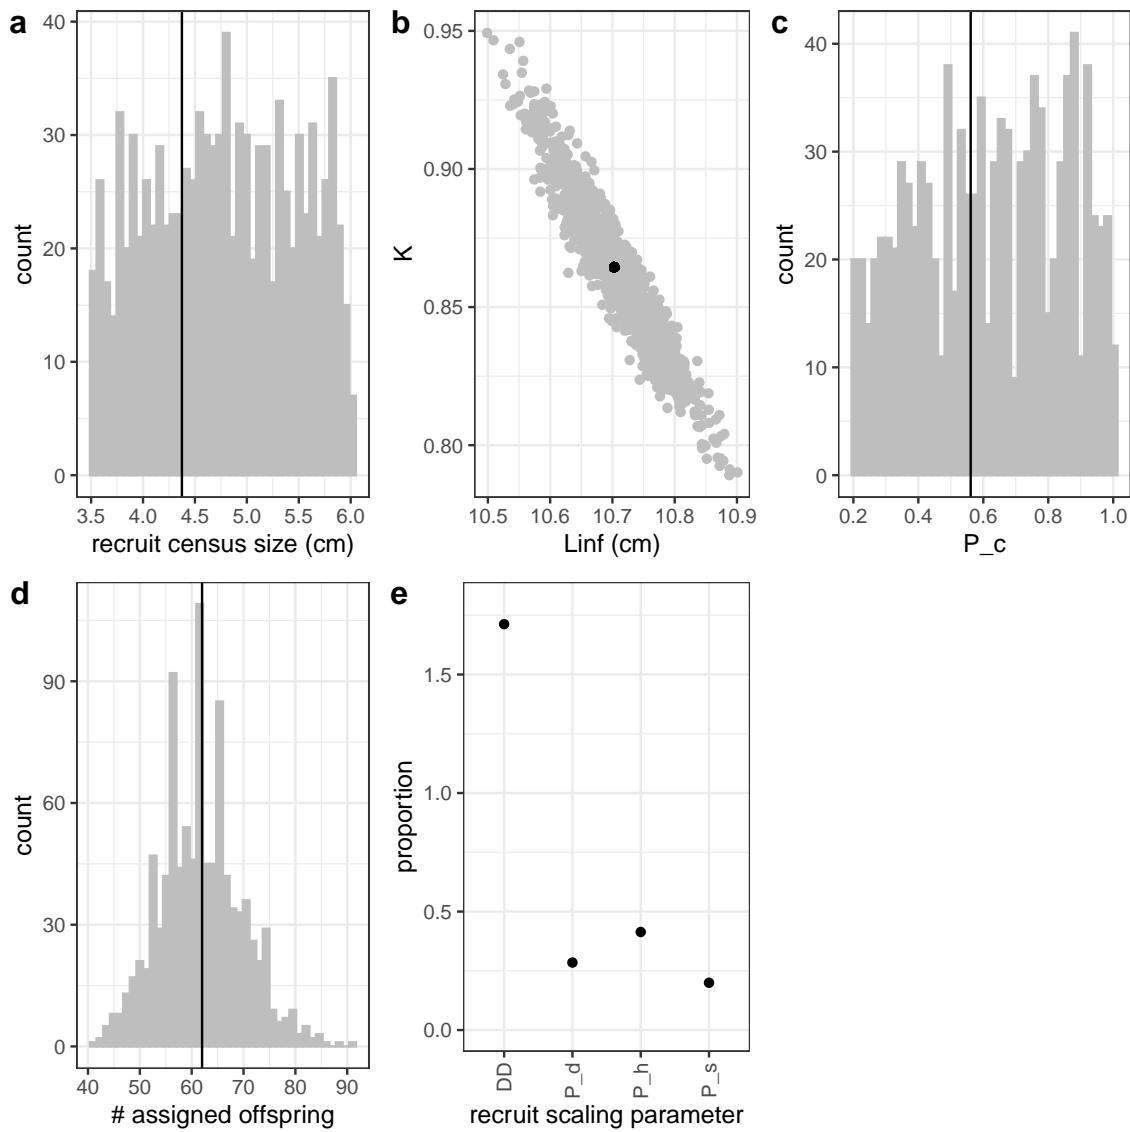

Figure B.6: Range of parameter inputs for uncertainty runs with all uncertainty included, where the black line or point is the value used for the best estimate: a)  $\text{size}_{\text{recruit}}$ , the census size at which fish are considered to have recruited after egg-recruit survival occurs; b) the parameters  $L_\infty$  and  $K$  of the von Bertalanffy growth model; c)  $P_c$ , the probability of capturing a fish; d) number of offspring assigned back to parents in the parentage analysis; e) factors that scale the number of estimated recruits from our site based on density-dependence in settler success (DD), proportion of the dispersal kernel captured by our sampling region ( $P_d$ ), the cumulative proportion of our sites we sampled over time ( $P_h$ ), and the proportion of our sampling area that is habitat ( $P_s$ ). 54

## B.2 Effects of different types of uncertainty on metrics

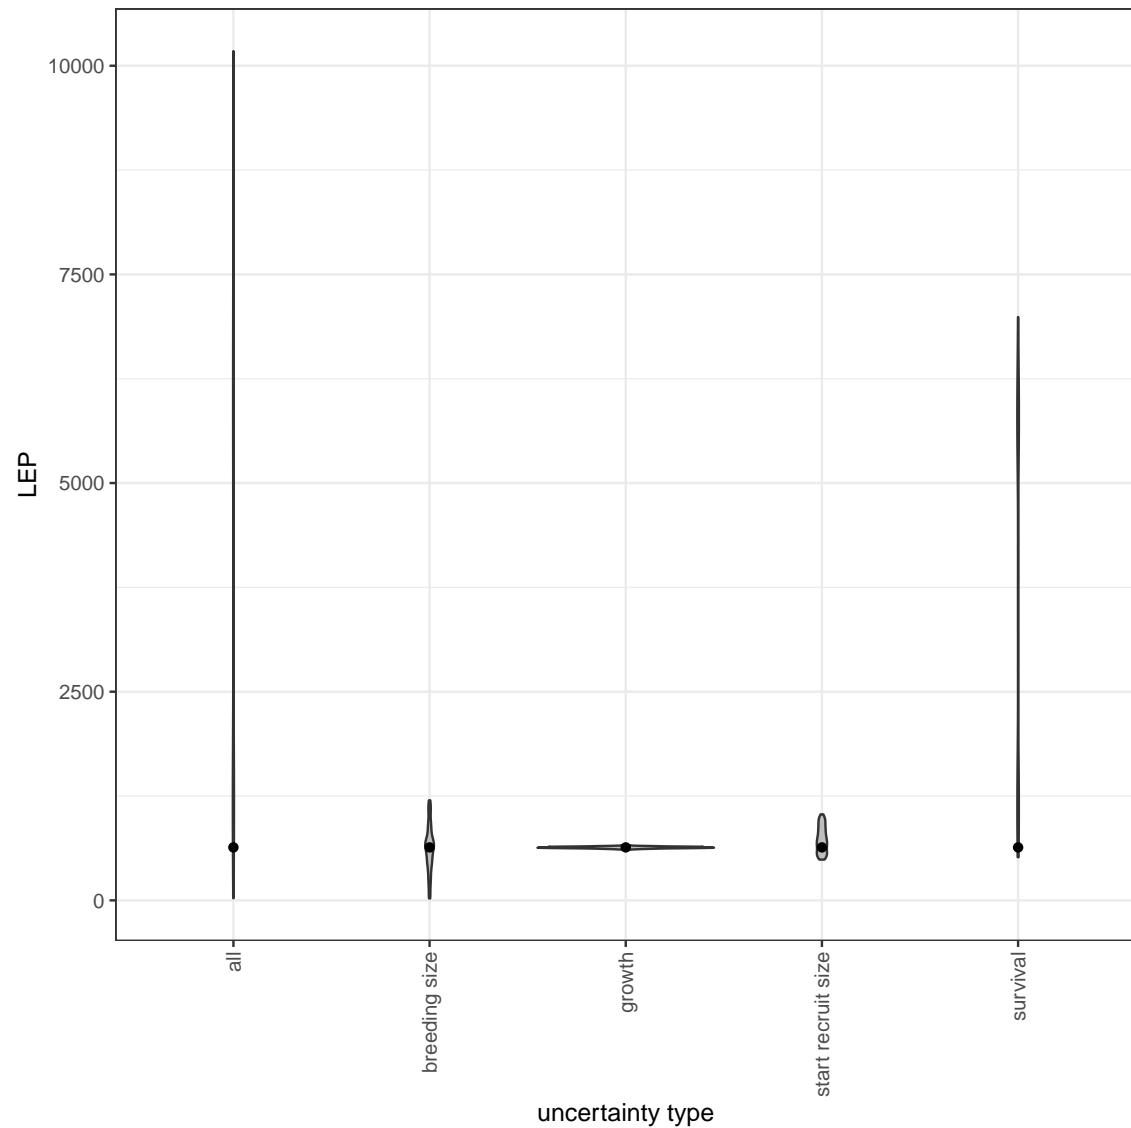

Figure B.7: The contribution of different sources of uncertainty in LEP.

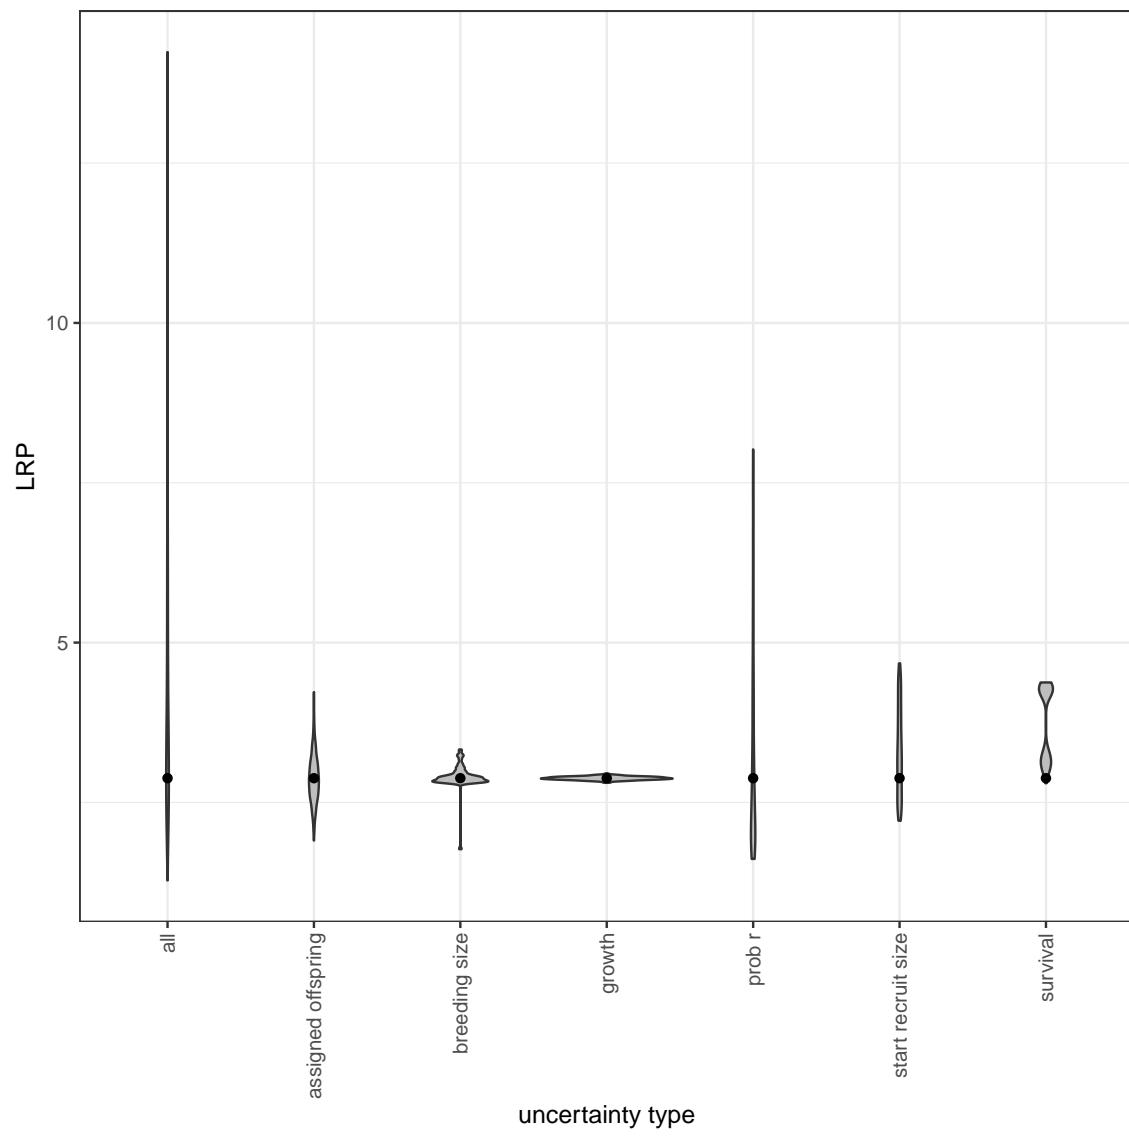

Figure B.8: The contribution of different sources of uncertainty in LRP.

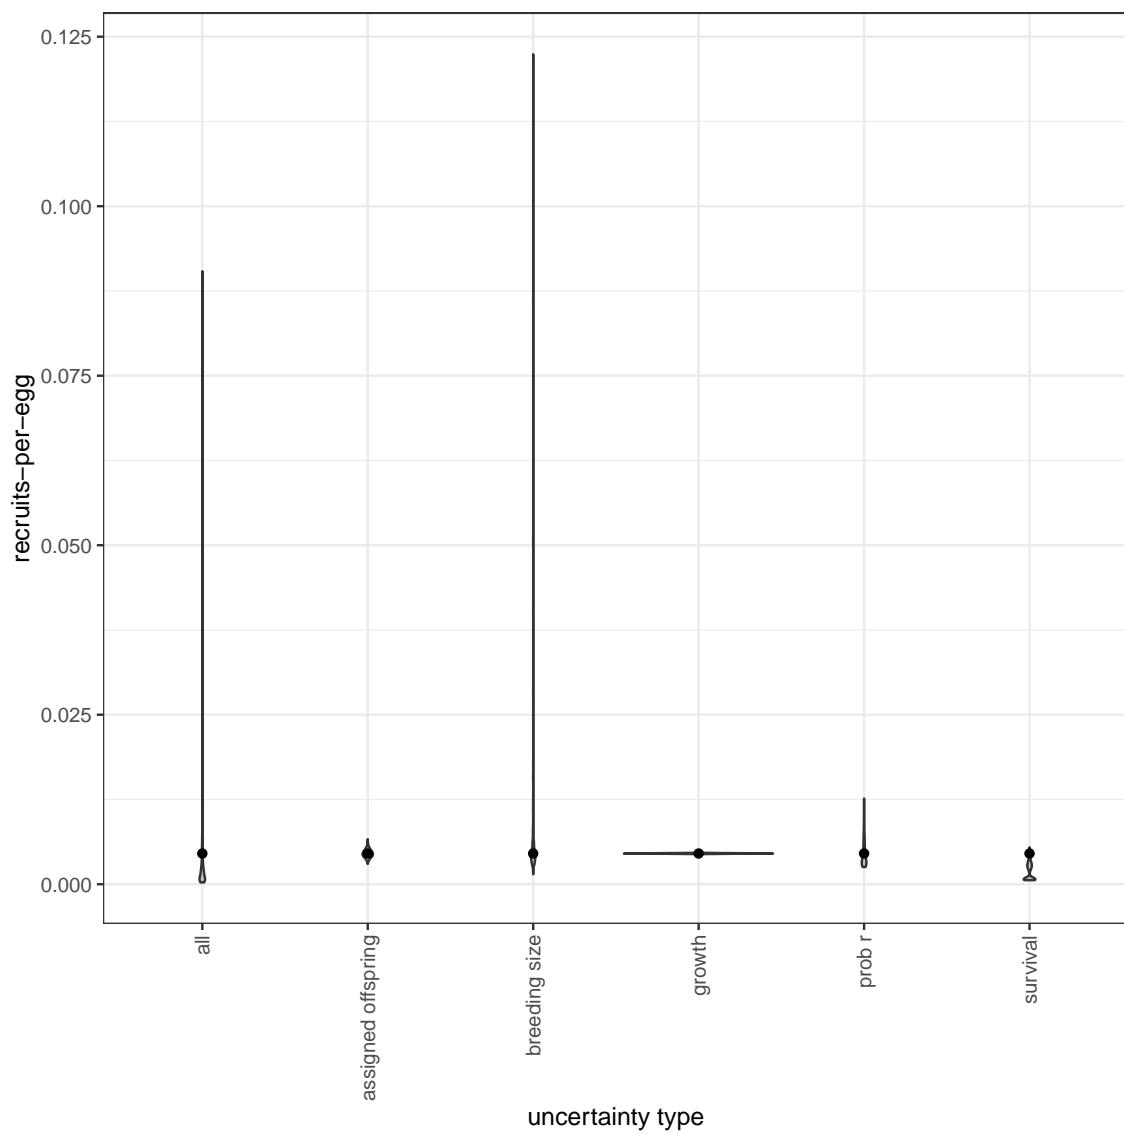

Figure B.9: The contribution of different sources of uncertainty in egg-recruit survival.

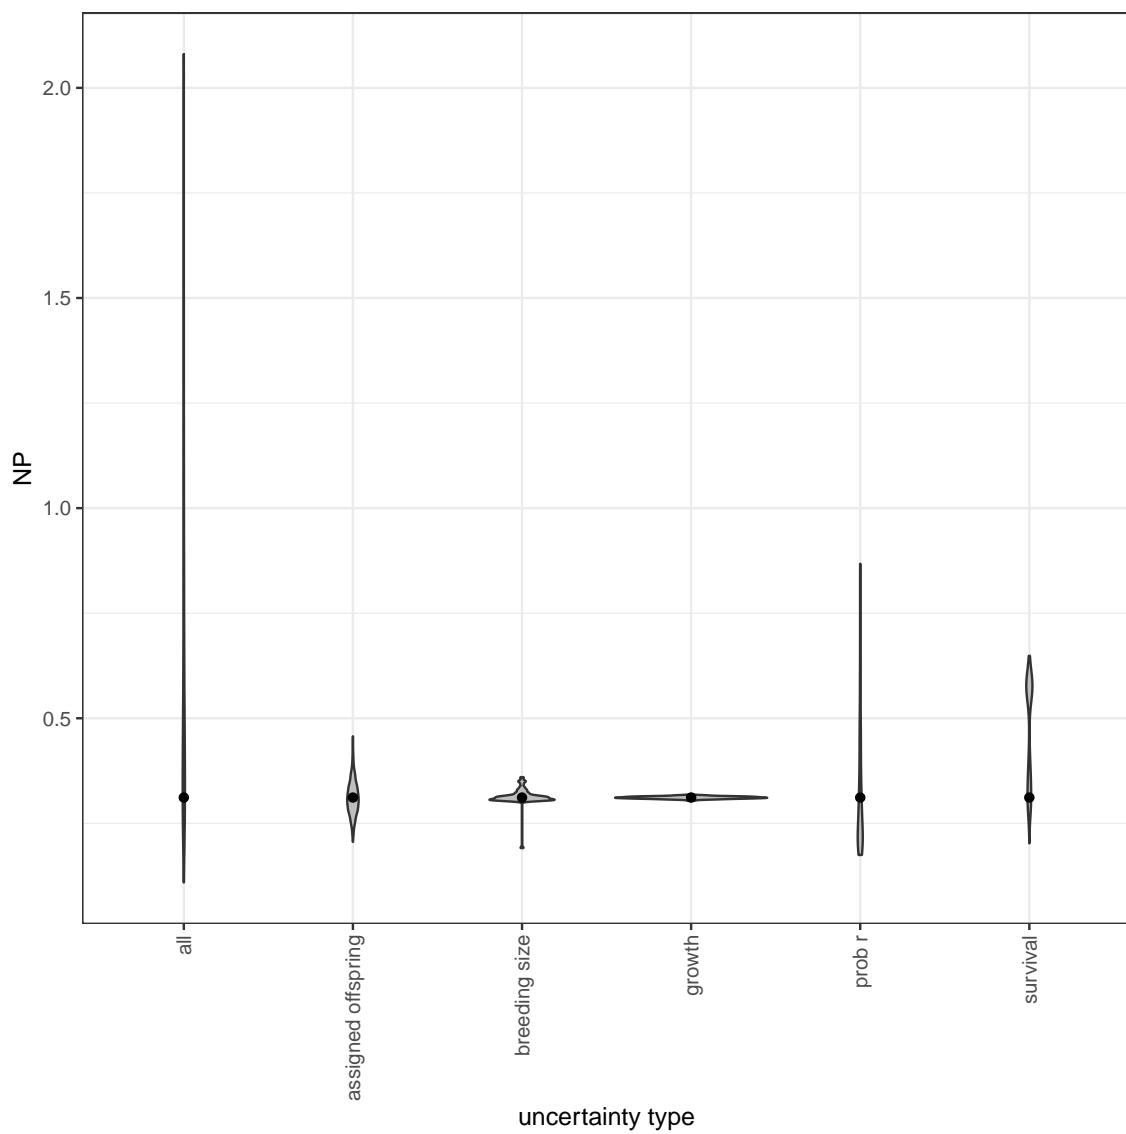

Figure B.10: The contribution of different sources of uncertainty in NP.
